New Foreword

On October 1, 2001 Axiom was withdrawn from the market and ended life as a commercial product. On September 3, 2002 Axiom was released under the Modified BSD license, including this document. On August 27, 2003 Axiom was released as free and open source software available for download from the Free Software Foundation's website, Savannah.

Work on Axiom has had the generous support of the Center for Algorithms and Interactive Scientific Computation (CAISS) at City College of New York. Special thanks go to Dr. Gilbert Baumslag for his support of the long term goal.

The online version of this documentation is roughly 1000 pages. In order to make printed versions we’ve broken it up into three volumes. The first volume is tutorial in nature. The second volume is for programmers. The third volume is reference material. We’ve also added a fourth volume for developers. All of these changes represent an experiment in print-on-demand delivery of documentation. Time will tell whether the experiment succeeded.

Axiom has been in existence for over thirty years. It is estimated to contain about three hundred man-years of research and has, as of September 3, 2003, 143 people listed in the credits. All of these people have contributed directly or indirectly to making Axiom available. Axiom is being passed to the next generation. I’m looking forward to future milestones.

With that in mind I’ve introduced the theme of the “30 year horizon”. We must invent the tools that support the Computational Mathematician working 30 years from now. How will research be done when every bit of mathematical knowledge is online and instantly available? What happens when we scale Axiom by a factor of 100, giving us 1.1 million domains? How can we integrate theory with code? How will we integrate theorems and proofs of the mathematics with space-time complexity proofs and running code? What visualization tools are needed? How do we support the conceptual structures and semantics of mathematics in effective ways? How do we support results from the sciences? How do we teach the next generation to be effective Computational Mathematicians?

The “30 year horizon” is much nearer than it appears.

Chapter 1

The Axiom System by James H. Davenport

This is (mostly) quoted verbatim, with permission, from Davenport[Dave92a].

1.1 A little history

In 1978 the present author spent two months at IBM Yorktown Heights, as part of the Computer Algebra Group, which had developed the Scratchpad-1 computer algebra system. Though this system never saw the light of day outside IBM, it was at the time a competitor for Macsyma and Reduce. All systems had struggled with the problems of writing ever more complicated algebraic algorithms, and handling the growth of the systems. Zippel has estimated that Macsyma, at its heyday, contained six different Gaussian elimination algorithms, whether because they were handling different data types, or because the authors were unaware of the other ones, or for more subtle reasons. Davenport[Dave81] had been having similar problems with Reduce, and a feeling of discontent among algorithm implementors was common.

The reactions of the computer algebra system-builders to the complexity are interesting to tabulate.
Macsyma embarked on the, ultimately futile, “new rational function” project, which was to have re-written much of the algebraic kernel in a more mathematically structured way, but which was unable to maintain backwards compatibility.

Reduce developed into Reduce 3, with its concept of domains, which meant that new constant domains could be added relatively simply. See Bradford et al. [Brad86]

Waterloo’s emerging team decided that none of the existing solutions was right, and opted for a new design based round a very small kernel, typically not knowing any algebra, and loadable modules, which would contain the algebraic knowledge of the system. This became the Maple system. Over the years, the definition of the kernel has changed, as it became obvious that certain algorithms, e.g. modular ones, could not be implemented efficiently in the interpreted modules.

MuMath and its successor Derive based themselves on the philosophy that “whatever fitted on a PC” was much closer to most users’ requirements than “the best possible mathematics”, and, in terms of the number of users, they are certainly correct.

IBM embarked on a lengthy period of algebraic reflection, prototyping and experimentation, sporadically reported in the literature Davenport & Jenks [Dave81a] and Jenks & Trager [Jenk81] first product of this process. Axiom is the end product of this process of reflection.

1.2 Axiom’s philosophy

Axiom shares with Maple the desire to build a system consisting of a kernel and loadable modules, written in an appropriately high-level language: the kernel knows very little algebra (in the classical sense of the term) and the modules define what algebraic facilities are present. The resemblance ends here, though. Maple’s modules are interpreted, sacrificing the ultimate in performance for small size and rapid loading, whereas Axiom’s modules are compiled into machine code for speed, much as in Reduce or Macsyma, but also for type analysis and constructing the database for the information system. There are certainly arguments in favour of Maple’s approach, though it does assume that the designers know a priori which primitives to build into the kernel to make a fast algebra system. Hence Maple is relatively fast at those operations for which it was designed, but attempts to make it into, say, a computational group theory package, have not been particularly successful, since the inner loops have been taking place in interpreted code. Another difference is, regretfully, that Axiom’s kernel is currently far larger than Maple’s, largely due to the genericity of the type system it implements.

Axiom’s kernel designers took the view that they did not know what algebraic facilities would be wanted, nor how they would be programmed. The only real assumption made was that the computations would be largely symbolic, and hence big integers, lists, vectors and trees were emphasised over, say, the efficient compilation of fixed-precision floating-point, which is left to externally-compiled code. There are also assumptions in the user interface about the wish to convert symbols into polynomials where appropriate, but these are in fact not fixed. The graphics facilities provided are more oriented towards the production of graphs of functions than other kinds of illustrations, but new facilities could easily be added.

Principle 1. **AXIOM has an interpreter for interactive use, much like any other system,**
and a compiler for creating new user-defined data types. The compiler emphasises strict type-checking, whilst the interpreter is more oriented towards ease of use.

The complexity of the algebraic facilities envisaged for Axiom required a data-typing mechanism over and above that provided by Lisp. To quote a very simple example, \(1 + x + x^2\) could be either a polynomial or a truncated Taylor series, but the square of the polynomial is \(1 + 2x + 3x^2 + 2x^3 + x^4\) whereas the square of the series is \(1 + 2x + 3x^2\). Similarly, if 2 represents the integer 2, then \(2 + 2 = 4\), whereas if 2 represents the congruence class \(\text{integers congruent to 2 modulo 3}\) then \(2 + 2 = 1\) (and, of course, \(4 = 1\) as well). Similarly, the list \((1,2)\) is not the same as the list \((2,1)\), but they should be regarded as the same if they represent (unordered) sets, and so on. In fact, the data typing requirements of computer algebra are so dynamic – the authors cannot predict what types the users will call for, explicitly or implicitly – and so rich that no existing language was suitable for expressing them. Hence the decision was taken that Axiom would have its own independent typing system.

This typing system, which underpins much of the rest of Axiom, has to solve the problems that Macsyma and Reduce have. Macsyma’s typing system suffers, essentially, from the \(n^2\) problem – every type has to know about every other type. This works when there are only a few types, and Macsyma has “general expression”, “rational function” (printed with \(/R/\)), and “Taylor series” (printed with \(/T/\)): adding more types would be difficult.

Reduce’s method of specifying domains is largely global: for example one specifies the modular domain by issuing the command on modular; One has then to be sure that all calculations are intended to be modular and that values being computed will not later be used as polynomial exponents, loop indices or whatever. There is much scope for hard-to-detect bugs in this area. The other drawback of Reduce’s scheme is that it really only applies to constant domains. This works well for floating point or complex coefficients, but has its weaknesses when it comes to handling Taylor series. For example

```
1: load tps;  % truncated power series;

2: ps(cos x,x,0);
   \{ 1 \quad 2 \quad 1 \quad 4 \quad 1 \quad 6 \quad 7 \}
   \{ 1 - (---)*x + (----)*x - (-----)*x + O(x )\}
   \{ 2 \quad 24 \quad 720 \}

3: ws-1;
   \{ 1 \quad 2 \quad 1 \quad 4 \quad 1 \quad 6 \quad 7 \}
   \{ - (---)*x + (----)*x - (-----)*x + O(x )\}
   \{ 2 \quad 24 \quad 720 \}

4: ps(sin x,x,0);
   \{ 1 \quad 3 \quad 1 \quad 5 \quad 7 \}
   \{ x - (---)*x + (-----)*x +0(x )\}
   \{ 6 \quad 120 \}

5:ws-x;
   1 \quad 3 \quad 1 \quad 5 \quad 7
```
The spurious power series expansion at line 6: is necessary to avoid the confusion at line 5:, where the variable $x$ is separated from the power series in $x$.

### 1.3 Axiom’s typing scheme

The typing scheme of Axiom can be described as a two-level typing scheme with single inheritance of types and multiple inheritance of meta-types. What does this mean, when stripped of the jargon? The first piece of jargon we wish to remove is the word “type”, which is so heavily used in computer science that it has practically ceased to have any meaning at all. The word that most nearly corresponds in Axiom is the word domain, as we shall see.

**Definition 1.** A domain is a set of values (possibly infinite), and the operations which can be performed on them.

This corresponds rather closely to a “data type” in much modern programming language theory.

**Principle 2.** Every internal Axiom data object belongs to one and only one domain.

Thus the integer “2” belongs to the domain `Integer`, whereas the congruence class modulo 3 “2” belongs to the domain `IntegerMod(3)`, which can also be written as `IntegerMod 3`, thanks to the following.

**Convention 1.** Juxtaposition corresponds to (unary) function application.

This corresponds with the traditional mathematical convention that $\sin x$ means the same as $\sin(x)$. The user should be warned, however, that juxtaposition has a high precedence, and that $\sin x**2$ parses as $(\sin x)**2$ and not as $\sin(x**2)$. This just shows the richness of mathematical notation that formal grammars of any kind find hard to capture.

Principle 2 can be seen in the following mini-session with Axiom:

```plaintext
->a:Integer
->b:IntegerMod(3)
->a:=2
  (3) 2
->a:=a+a
  (4) 4
->b:=2
  (5) 2
```
1.3. AXIOM’S TYPING SCHEME

->b:=b+b

(6) 1

The first two lines declare the domains to which the values of a and b may belong – loosely speaking the types of the variables a and b – then they are given values, which are added. As we said earlier, \( a + a = 4 \), whereas \( b + b = 1 \). This may appear confusing, so let’s run though the same session, but asking Axiom to print out the domains of the various values. This is done by means of the system command \texttt{set message type on}.

**Convention 2 (borrowed from APL).** All system commands, i.e. those that do not perform, or affect the performance of, algebraic operations, begin with \texttt{)}. In general, they may be contracted as far as is unambiguous, so that \texttt{)set message type on} can be contracted as far as \texttt{)set message type on}.

In addition to the Hyperdoc help system, information about system commands can be found using \texttt{)help}.

\[-a:Integer \quad \text{Type: Void}
\]  
\[-b:Integer\text{Mod}(3) \quad \text{Type: Void}
\]  
\[-a:=2 \quad \text{(3) 2} \quad \text{Type: Integer}
\]  
\[-a:=a+a \quad \text{(4) 4} \quad \text{Type: Integer}
\]  
\[-b:=2 \quad \text{(5) 2} \quad \text{Type: Integer\text{Mod} 3}
\]  
\[-b:=b+b \quad \text{(6) 1} \quad \text{Type: Integer\text{Mod} 3}
\]

Note that the declarations themselves are algebraic commands, and therefore their results must belong to a domain: in this case the \texttt{Void} domain. The numbers before the values can be used to refer to these values later.

**Convention 3.** The symbol \% refers to the most recently computed proper value (i.e. not of the \texttt{Void} domain). \%\( n \), or \%\texttt{n}, refers to the value numbered \( n \), if \( n \) is a positive integer. If \( n \) is a negative integer, \%\( n \) refers to the value of the \(|n|\)‘th previous step. Also, \%\texttt{pi} refers to \( \pi \), \%\texttt{e} to \( e \approx 2.718281828 \) and \%\texttt{i} to \( \sqrt{-1} \).

Note that \% is not a synonym for \%\texttt{(-1)}, since if the previous step were a declaration, then \%\texttt{(-1)} would belong to the domain \texttt{Void}, whereas % would refer to the last non-void object.

Principle 2 has an apparent exception, which we can see in the example above if, instead of writing \texttt{a:=a+a}, we had just tried \texttt{a+a}, i.e. asked for the value to calculated, but not to
replace the old \( a \).

\[
\text{\texttt{->a*a}}
\]

\[
\begin{array}{c}
\text{Type: PositiveInteger} \\
\end{array}
\]

The \( 4 \) now belongs to \texttt{PositiveInteger} whereas it used to belong to \texttt{Integer}, yet we are performing the same calculation. The answer is that \texttt{PositiveInteger} is not actually a separate domain from \texttt{Integer}, rather it is a \texttt{sub-domain} (a concept we shall define formally later). Whilst it is possible for users to add new sub-domains to Axiom, there are two built-in ones, with the inclusion relationships

\[
\text{PositiveInteger} \subset \text{NonNegativeInteger} \subset \text{Integer}
\]

and a general rule about \texttt{Union} domains that will be explained later. An element of a domain which is also an element of a sub-domain can move freely to a larger sub-domain, or to the whole domain, as required. The reason for the existence of these sub-domains is to allow more thorough type-checking: for example a square matrix has to have a dimension which is a \texttt{NonNegativeInteger}, and it only makes sense to raise polynomials to \texttt{NonNegativeInteger} powers. Similarly, the argument to \texttt{IntegerMod} must be a \texttt{PositiveInteger}. In order to make \texttt{interactive} use easier, the interpreter will automatically convert elements of sub-domains into those sub-domains. This can be summarised as follows.

**Principle 3.** \textit{Values can freely move from sub-domains to larger ones, and, in the interpreter only, in the other direction, provided that this conversion is legitimate.}

Compilers clearly can’t move from a large domain to a smaller one, since they have no idea whether such a contraction will always be possible – if the programmer knows that it will always be possible, they have to declare the fact.

### 1.3.1 Aren’t all these types confusing?

The casual user need not concern themselves with the type system: those functions that most other systems provide, and which correspond to general algebra and calculus, work through the type system provided. For example, the following session could be taken from any algebra system.

\[
\text{\texttt{->sin(x)}}
\]

\[
\begin{array}{c}
\text{(1) sin(x)} \\
\end{array}
\]

\[
\text{\texttt{->integrate(%,x)}}
\]

\[
\begin{array}{c}
\text{(2) - cos(x)} \\
\end{array}
\]

\[
\text{\texttt{->series(%,x=%pi/2)}}
\]

\[
\begin{array}{c}
\text{(3)} \\
\end{array}
\]

\[
\begin{array}{cccccccc}
\%pi & 1 & \%pi & 3 & 1 & \%pi & 5 & 1 \\
(\text{x - } \ldots) & - & (\text{x - } \ldots) & + & (\text{x - } \ldots) & - & (\text{x - } \ldots) \\
2 & 6 & 2 & 120 & 2 & 5040 & 2 \\
+ \\
1 & \%pi & 9 & 1 & \%pi & 11 & \%pi & 12 \\
\ldots & (\text{x - } \ldots) & - & \ldots & (\text{x - } \ldots) & + & O((\text{x - } \ldots) )
\end{array}
\]
We note that the second use of integrate did not require, and indeed can not be given, a variable. Since the expression is a series in \( x - \pi/2 \), it can only be integrated with respect to \( x \), and the type system ensures this. In fact the domains of these results are, respectively, Expression Integer, which is the workhorse for much of calculus, Union(Expression Integer,List Expression Integer) and UnivariatePuiseuxSeries(Expression Integer,x,%pi/2) for the last two. These last two require some explanation, which is given in the section 1.4 “Some AXIOM facilities” on page 8.

Axiom naturally manipulates various types of composite data structures: lists, vectors, sets and so on.

Convention 4 (a convention of the library, rather than of the kernel). Parentheses \(-()\) are used for grouping and function application, brackets \([-]\) are used for constructing lists, and braces \(-\{\}\) are used for constructing sets.

The difference between lists and sets is that lists can contain repetitions, and order matters, whereas sets, as in mathematics, are unordered and without repetition.

\[-\{2,1,2,1\}\]

\(\text{Type: List PositiveInteger}\)

\[-\{2,1,2,1\}\]

\(\text{Type: Set PositiveInteger}\)

Suppose we had a list of objects, and wished to convert it into a set, e.g., in the situation above, we do not want to retype the 2,1,2,1. This is handled by a very general mechanism in Axiom.

Convention 5. The :: in x operator, used as in

\[\text{Axiom object :: Axiom domain}\]

can be used to convert the object to lie in the specified domain.

The :: operator is partially built into the Axiom kernel. When new data types are defined, the definition includes some coerce functions between the new type and some existing types. However, the :: operator is more than just one of these programmed conversions: it is at least what an algebraist would call the transitive closure of these operations, so that if there are coerce functions from A to B , and from B to C , then :: can convert from A to C . In
fact, it is more than this: if a functor, such as $\text{List}$ possesses a $\text{map}$ operation of signature

$$(A \to B, \text{List} A) \to \text{List} B$$

and it is possible to coerce objects from $A$ to $B$, then the system will be able to coerce objects from $\text{List} A$ to $\text{List} B$. More details are given in Sutor & Jenks [Jenk92].

**Principle 4.** The interpreter is responsible for performing any chain of coercions necessary to understand the user’s intentions, or when required to do so by an explicit use of $::$. The compiler will perform a chain of coercions when instructed to do so by the $::$ operator in compiled code.

So we could replace command (2) above by

$$\text{->\%::Set PositiveInteger}$$

```
(2) \{1,2\}
```

Type: Set PositiveInteger

A large number of coercions are performed automatically. Even the simple computation $x + 1$ causes three coercions:

1. the variable $x$ from the domain $\text{Variable}$ to the domain $\text{Polynomial Integer}$;
2. the number $1$ from the domain $\text{PositiveInteger}$ to the domain $\text{Polynomial Integer}$, passing via $\text{Integer}$;
3. the result $x + 1$ from the domain $\text{Polynomial Integer}$ to the domain $\text{OutputForm}$, using sub-coercions of $x$ and $1$ to $\text{OutputForm}$.

All printing actually takes place from the domain $\text{OutputForm}$, which is also the starting point for conversions to TeX format, Fortran etc. This means that a new domain which can be printed at all (i.e. which can be coerced to $\text{OutputForm}$) can be printed in TeX, Fortran and indeed in any other ways that get added later, without having to modify the domain at all.

### 1.4 Some AXIOM facilities

Computer algebra is often also called “symbolic manipulation”, and Axiom excels at manipulating symbols as such. A symbol can be as simple as $x$ or as complex as

$$\Omega \text{ (theta)}$$

```
(1) x (a,b )
    7 1,2 1
```

obtained via the following command:

```
script(x,[[1,2],[paren theta],[Omega],[7], [a,script(b, [[1]])]])
```

This symbol can be converted into TEX format by means of the $\text{outputAsTex}$ function: the result is shown below.

$$\Omega \text{ x (theta) } 7 x_{1,2} (a, b_1)$$

It is still a single symbol, and the command

$$\text{->\%::\%}$$

```plaintext
Omega (theta)
```
1.4. SOME AXIOM FACILITIES

(4) \[ - \cos(\ x\ (a,b)) \]

\[ 7\ \ 1,2\ \ 1 \]

Type: Union(Expression(Integer),...)

is no different from \texttt{integrate(sin(x),x)}.

Axiom has a rich integrator, based on the developments by Bronstein[Bron90a]. As we saw earlier, and just above, it seems to give a rather complicated domain* for the result: why not just \texttt{Expression Integer}? This expression certainly looks like an expression with integer entries, and seems to behave as one. First, we need to explain what \texttt{Union} is.

**Principle 5.** Any set of Axiom domains \(D_1,\ldots,D_n\) can be combined into a (disjoint) union domain, denoted \texttt{Union}(\(D_1,\ldots,D_n\)). The \(D_i\) are called the branches of the union. The operations available on this union domain are:

- equality – two elements are equal if they come from the same branch and are equal in that branch;
- coercion to OutputForm;
- coercion from each \(D_i\) to the union domain;
- coercion to each \(D_i\) from the union domain, which may fail if the union object is not in the correct branch;
- an \texttt{in x} predicate case, for testing if the union object actually is in a particular branch or not.

These union domains correspond to what some other languages call “sum types”. A particularly useful case is exemplified by the “exact quotient” operation on \texttt{Integer}: its return type is \texttt{Union(Integer,“failed”),} where the special token \texttt{failed} is returned if the division is not exact.

So we are saying that Axiom’s integrator can return either an expression, or a list of expressions. A simple example of it doing the latter is the following.

\texttt{-&gt; integrate(1/(x**2-a),x)}

\begin{equation}
2
\begin{array}{c}
2
(x + a) \\| a - 2a x \\
\log(---------------------)
\end{array}
\begin{array}{c}
x\| - a \\
2
\end{array}
\end{equation}

\begin{equation}
(4) \[------------------------,- -------------\]
\begin{array}{c}
+--
\end{array}
\begin{array}{c}
2\|a
\end{array}
\begin{array}{c}
\| - a
\end{array}
\end{equation}

Here, there are two possible answers, depending on the sign of \(a\). Since Axiom has no way of knowing which is required, it returns both, and leaves it to the user, or the caller of the \texttt{integrate} command, to supply the higher knowledge necessary to determine which element of the list to use (and it may not always be the same one). In some sense, they are equally correct, as we can check by differentiating them.

\texttt{-&gt; [differentiate(f,x) for f in %]}

\begin{equation}
1
\begin{array}{c}
1
\end{array}
\begin{array}{c}
2
x - a
\end{array}
\begin{array}{c}
x - a
\end{array}
\end{equation}

\begin{equation}
(5) \[------,------\]
\begin{array}{c}
2\|a
\end{array}
\begin{array}{c}
\| - a
\end{array}
\end{equation}
Note the neat way of handling the list. There are many other such list handling techniques, and the user can also use `map`, a function provided on most of the library’s compound data types. This is how map could differentiate the elements of that list.

```
-> map(f+->differentiate(f,x),%% 4)
```

```
1 1
2 2
x - a x - a
```

**Convention 6 (Of the library authors).** The notation

```
list of variables + - > expression
```

defines an anonymous function of those variables. It corresponds to the lambda-calculus expression “list of variables.expression”.

As we have already seen, Axiom has a powerful series capability. As pioneered by Norman [Norm75] in Scratchpad-1, these series are lazy: terms are only evaluated as required for printing, and more terms can always be evaluated as required.

```
-> series(sin(x),x=0)
```

```
1 3 1 5 1 7 1 9 1 11 12
x - - x + ---- x - ----- x + ------- x - -------- x + 0(x )
6 120 5040 362880 39916800
```

(2) `-> %/x`

```
1 1 3 1 5 1 7 1 9 1 11 12
x - x - -- x + ---- x - ----- x + ------- x - -------- x + 0(x )
x 6x 120x 5040x 362880x 39916800x
```

(3) `-> %-1`

```
1 1 3 1 5 1 7 1 9 1 11
x - 1 + - x - -- x + ---- x - ----- x + ------- x + 0(x )
x 6x 120x 5040x 362880x
```

The number of terms initially calculated (and therefore displayed) is controlled by the system command `)set streams calculate`. The type of this result is `UnivariatePuiseuxSeries(Expression Integer,x,0)`.

The last two parameters are clearly the variable and the point about which we are expanding, but what on earth is a Puiseux series? Why cannot Axiom give us the familiar Taylor series, which this certainly looks like being? A Taylor series represents a continuous function $a_0x^0 + a_1x^1 + \cdots$. One way of generalising this is to allow meromorphic functions, i.e. those with a point singularity of the $1/x$ (more generally $1/x^n$) variety. In order to represent these, we have to allow (a finite number of) negative exponents in the series – so-called Laurent series.

```
-> series(1/sin(x),x=0)
```

```
- 1 1 7 3 31 5 127 7 73 9 10
x + - x + ---- x + ----- x + ------- x + -------- x + 0(x )
6 360 15120 604800 3421440
```
1.4. SOME AXIOM FACILITIES

However, even these are not as general as one would like, since they are incapable of representing multi-valued functions like \( \sqrt{x} \). To do this, we have to allow fractional exponents (of bounded denominator), which gives us Puiseux series.

\[
\begin{align*}
\text{-> sqrt \%} \\
& \quad \begin{array}{cccc}
1 & 3 & 7 \\
- & - & - \\
2 & 1 & 2 & 1 & 2 & 5 \\
\end{array} \\
\text{\quad (5) } x & + \quad -\frac{1}{12} x & + \quad -\frac{1}{160} x & + O(x) \\
\text{-> \%**2} \\
& \quad 9 \\
& \quad - \\
& \quad \begin{array}{cccc}
1 & 1 & 7 & 3 & 2 \\
\end{array} \\
\text{\quad (6) } x & + \quad -\frac{1}{6} x & + \quad -\frac{1}{360} x & + O(x) \\
\text{(7) -> \%%(4)-\%} \\
& \quad 19 \\
& \quad - \\
& \quad \begin{array}{c}
2 \\
\end{array} \\
\text{\quad (7) } O(x) \\
\end{align*}
\]

Note that Axiom, like any other algebra system, cannot prove that the difference of these two series is identically zero, merely that in going all the way up to the limit required by \( \text{set streams calculate} \), it can find no non-zero terms. Puiseux series have many uses in algebraic geometry. See Davenport[Dave81]

1.4.1 How does one keep track of all this?

There seem to be so many different names and domains around in the Axiom system. How does one keep track of them all, and know what to use? There is an on-line help system Hyperdoc, with tutorial material and information arranged by subject, but the system itself provides some help.

**Convention 7.** The names of Axiom functions are either special symbols (such as +) or complete english words strung together. In this case, every word after the first is capitalised. Thus \text{integrate} but \text{complexIntegrate}. In addition:

- all boolean predicates end in a ? , as in odd?, which tests if a number is odd
- all destructive functions which operate on data structures end in a ! , as in \text{reverse!}, which reverses a list destructively.

Conversely, the names of domains (and other constructors we will come to later) consist of english words strung together, all of which are capitalised, as in \text{IntegerMod} or \text{UnivariatePuiseuxSeries}.

One can search (case-insensitively) for all functions whose name contains a particular word by using the system command \( \text{)what operations} \), contractible to \( \text{)w o} \), as in

\[
\text{->)}\text{what operations series}
\]
Operations whose names satisfy the above pattern(s):

\begin{verbatim}
series seriesSolve
\end{verbatim}

To get more information about an operation, say \texttt{series}, issue the command \texttt{)display op series}.

As it says, the command \texttt{)display operations}, contractible to \texttt{)do}, can be used to find out what the arguments of an operation should be. However, in order to explain this, we have to delve rather deeper into Axiom's type system. The user of the Nag Fortran library sees nothing strange in writing one subroutine to multiply real matrices, and a different one to multiply complex matrices. Indeed, one would be hard put to do anything else in Fortran 77. The user of the Nag Ada library, in contrast, would expect to find a generic matrix multiplication routine, which could be called for any built-in real or complex type, and possibly for additional user-defined types. Axiom's type system is much closer to the Ada one than the Fortran one, but in fact even more general than the Ada model.

Just as one can make various different modular domains by applying the functor$^1$ \texttt{IntegerMod} to different integers, so one can make different matrix domains by applying the functor \texttt{Matrix} to different domains for the coefficients.

\begin{verbatim}
-> [[1,2],[3,4]]::Matrix IntegerMod 3
   +1 2+ (1) | | +0 1+
   Type: Matrix(IntegerMod(3))

-> [[1,2],[3,4]]::Matrix IntegerMod 5
   +1 2+ (2) | | +3 4+
   Type: Matrix(IntegerMod(5))

(3) -> [[1,2],[3,4]]::Matrix Float
   +1.0 2.0+ (3) | | +3.0 4.0+
   Type: Matrix(Float)
\end{verbatim}

In each case, the coefficient arithmetic is done according to the correct rules of the coefficient domain.

\begin{verbatim}
(4) -> %%(1)**2
   +1 1+ (4) | | +0 1+
   Type: Matrix(IntegerMod(3))

(5) -> %%(2)**2
   +2 0+ (5) | | (5) | | +0 1+
   Type: Matrix(IntegerMod(3))
\end{verbatim}

$^1$ Axiom terminology, borrowed from category theory, uses the word “functor” for those functions that yield domains as their result, whereas “function” is reserved for operations whose value is an Axiom object.
1.5. **CATEGORIES**

(5) \[\begin{array}{c|c}
    0 & 2 \\
\end{array}\]  
Type: Matrix(IntegerMod(5))

(6) \[\begin{array}{c|c}
    7.0 & 10.0 \\
\end{array}\]  
Type: Matrix(Float)

But would it make sense, say, to have a matrix of hash tables? Clearly not: we require that the coefficients of the matrix be capable of being added, subtracted, multiplied etc. In fact, we have to place some requirements on the domain which is the parameter to Matrix, just as we placed some requirements on the argument to IntegerMod. The \texttt{show} command tells us what these requirements are (and a great deal more).

\texttt{->)show IntegerMod}
\begin{quote}
IntegerMod p: PositiveInteger is a domain constructor
Abbreviation for IntegerMod is ZMOD
\end{quote}

\texttt{->)show Matrix}
\begin{quote}
Matrix R: Ring is a domain constructor
Abbreviation for Matrix is MATRIX
\end{quote}

We have stipulated that the Axiom object \texttt{p} which is the parameter to IntegerMod must belong to the (sub-)domain \texttt{PositiveInteger}, and similarly we stipulate that the domain \texttt{R} which is the parameter to Matrix must belong to the second-order type system \texttt{Ring}.

### 1.5 Categories

**Principle 6.** The Axiom library declares a family of second-order types, known as categories. The categories are arranged in a directed acyclic graph, and each domain belong to a specific category, and to all the ancestors of that category. The specification of a category includes
- all its direct ancestors,
- any additional operations that this category supports, and
- any additional axioms that the operations must satisfy.

The operation \texttt{Join} is used to construct new categories.

This may appear a bit abstract, so let’s look at an example from the foundations of the Axiom library. The fundamental category in Axiom is \texttt{SetCategory}.

**Convention 8.** Whenever a category, or domain, is being discussed in Axiom, the symbol \% stands for the domain in question, or for any domain from the category in question.

With the help of that notation, we can ask Axiom what the definition of \texttt{SetCategory} is.

\texttt{->)show SetCategory}
\begin{quote}
SetCategory is a category constructor.
Abbreviation for SetCategory is SETCAT
This constructor is exposed in this frame.
Issue \texttt{)edit bookvol10.2.pamphlet} to see algebra source code for SETCAT
\end{quote}
CHAPTER 1. THE AXIOM SYSTEM BY JAMES H. DAVENPORT

--- Operations ---

\[ ?=?: (%,%) \rightarrow \text{Boolean} \quad \text{coerce} : % \rightarrow \text{OutputForm} \]

This output shows that there are two operations defined on any domain, denoted by \%, which belongs to the category \text{SetCategory}: an infix operation \( = \) which takes two arguments from \% and yields a \text{Boolean} result, and an operation called \text{coerce}, which takes an element of \%, and yields an \text{OutputForm}. How does this grow into more useful categories? A graphic representation of some of the first few extensions is given below.

\[
\text{SetCategory} \quad \downarrow \quad \text{AbelianSemiGroup} \quad \downarrow \quad \text{AbelianMonoid} \quad \downarrow \quad \text{CancellationAbelianMonoid} \quad \downarrow \quad \text{AbelianGroup} \\
\downarrow \quad \text{OrderedSet} \quad \downarrow \quad \text{OrderedAbelianMonoid} \quad \downarrow \quad \text{OrderedCancellationAbelianMonoid} \quad \downarrow \quad \text{OrderedAbelianGroup}
\]

where the arrows indicate a “direct descendant” relationship.

\text{AbelianSemiGroup} is defined to have one new operator:

\[ + : % \times % \rightarrow % \]

satisfying the associative and commutative axioms:

\[ a + (b + c) = (a + b) + c \]

\[ a + b = b + a \]

\text{AbelianMonoid} introduces a new nullary operator\(^2\)

\[ 0 : \rightarrow % \]

satisfying the obvious axiom

\[ 0 + a = a \]

\text{CancellationAbelianMonoid} is the category of abelian monoids with the cancellation axiom:

\[ a + b = a + c \Rightarrow b = c \]

Constructively, this is represented by a partial subtraction operator, whose signature is defined as:

\[ - : % \times % \rightarrow \text{Union}(%, "failed") \]

While such an operation could be defined for any \text{AbelianMonoid}, or even any \text{AbelianSemiGroup}, it is the cancellation axiom that ensures that \( - \) has a unique value. This operator is subsumed in the \( - \) operation defined on \text{AbelianGroups}.

---

\(^2\) Technically speaking, it is a constant, rather than a nullary operator, which means that the value is computed once and for all when the type is created. The difference is essentially one of efficiency, and we will not discuss it further here.
AbelianGroup adds one further unary operator \(^3\)

\[- : \% \rightarrow \%
\]

This operator satisfies the axiom

\[a + (-a) = 0\]

The first \(\searrow\) introduces an operator

\[< : \% \times \% \rightarrow Boolean\]

satisfying the usual axioms:

\[a < b \vee b < c \Rightarrow a < c\]

\[\neg(a < b) \vee \neg(b < a) \Rightarrow a = b\]

\[a < b \Rightarrow \neg(b < a)\]

Subsequent \(\searrow\) in this diagram introduce no new operators, but one more axiom is introduced, when OrderedAbelianSemiGroup is defined:

\[a < b \Rightarrow a + c < b + c\]

This is typical of what happens when two categories are merged to form a new named category: we keep the same operators, but are interested in the interaction between them, which requires the introduction of new axioms to define this interaction. Subsequent \(\searrow\) in the chain represent the straightforward merging of ancestors.

It should be noted that none of these definitions are hard-coded in the Axiom kernel: merely the mechanism for understanding them is part of the kernel. The definitions are written in the Axiom category definition language, and could be modified or extended to suit different kinds of mathematics. See Lambe [Lamb89], Schwarz [Schw88]. The code reads, in essence, as given below.

**Convention 9.** Axiom comments can be introduced by \(--\) or \(++\). Those beginning \(++\) are intended for the user, and can be retrieved by the on-line help system.

For example, the comment following zero? in AbelianMonoid is retrieved when the operation name zero? is searched for.

\[SetCategory():\text{Category} == \text{Join(Object, CoercibleTo OutputForm)}\text{ with}\]

\["=": (\%,\%) \rightarrow \text{Boolean}\]

\(^3\) In practice, it also adds a binary operator

\[- : \% \times \% \rightarrow \%
\]

satisfying the axiom

\[a - b = a + (-b)\]

From a logical point of view, the binary operator is redundant. It is present in Axiom for two reasons. The first is legibility of programs: \(a - b\) is easier to read than \(a + (-b)\). The second is efficiency: while the binary operator can always be implemented in terms of the unary operator, and indeed has a default definition implementing it this way, it is not necessarily very efficient to do so. For example, if \% is a matrix type, implementing the binary operator in terms of the unary operator causes two new matrices to be allocated instead of one.
++ Axioms:
++ associative("+":(%,%)->%) || space{ (x+y)+z = x+(y+z) }
++ commutative("+":(%,%)->%) || spad{ x+y = y+x }
AbelianSemiGroup(): Category == SetCategory with
"+": (%,%) -> %
++ Axioms:
++ leftIdentity("+":(%,%)->%,0) || spad{ 0+x=x }
++ rightIdentity("+":(%,%)->%,0) || spad{ x+x=x }
AbelianMonoid(): Category == AbelianSemiGroup with

0: constant -> % ++ 0 is the additive identity element

zero?: % -> Boolean ++ zero?(x) tests if x is equal to 0

add

zero? x == x = 0

The clause after add introduces a default definition of zero? in terms of = and 0.

**Principle 7.** Categories can introduce default definitions of operations, which will take effect in any domain belonging to that category unless overridden by a definition in that domain, or in a more specific category.

Further details of the general mechanism are given in Jenks et al. [Jenk92], and the actual categories implemented in the Axiom library are described in Davenport & Trager [Dave90] and Davenport et al. [Dave91]. However, we can see that it is possible to define such a system of categories which will act, in effect, as a type system for the domains themselves.

**Principle 8.** The functors of Axiom are strongly typed: each parameter which is an Axiom object is specified to come from a particular domain; each parameter which is an Axiom domain is specified to belong to a particular Axiom category. Similarly, the domain returned by a particular functor is specified to belong to a particular category. All construction of domains must satisfy these constraints on the functors.

To take the example of Matrix, the definition of the functor could begin as follows:

Matrix(R:Ring): MatrixCategory(R, Vector R, Vector R) ==

where MatrixCategory is a category, itself with three parameters, which defines the various operations that must be satisfied by all kinds of matrices, not just those defined by Matrix, which defines dense matrices stored in a two-dimensional array with no special properties.

We can discover what Axiom’s current definition of the operations on a ring are.

-> )show Ring

Ring is a category constructor
Abbreviation for Ring is RING

This constructor is exposed in this frame.

Issue )edit bookvol10.2.pamphlet to see algebra source code for RING

--------------- Operations -----------------------------

?*?: (%,%) -> %   ?*?: (Integer,%) -> %
?*?: (NonNegativeInteger,%) -> %   ?*?: (PositiveInteger,%) -> %
?**?: (%,%),NonNegativeInteger) -> %   ?**?: (%,%),PositiveInteger) -> %
?+?: (%,%) -> %   ?-?: (%,%) -> %
?-?: % -> %   ?=?: (%,%) -> Boolean
1.5. CATEGORIES

In particular we have the operations of addition, subtraction and multiplication that are required to make sense of the definition of matrix with entries from \( R \). In fact the actual definition of \texttt{Matrix} is more complicated, and the category of the result is defined to be \texttt{Matrix}\( (\texttt{Ring}) \): \texttt{MatrixCategory}(\texttt{Ring},Row,Col) \) with

\[ \text{diagonalMatrix} : \text{Vector} \texttt{R} \to \% \]
\[ ++ \backslash\texttt{spad}(\text{diagonalMatrix}(v)) \text{ returns a diagonal matrix where the elements } ++ \text{ of } v \text{ appear on the diagonal.} \]

\text{if } \texttt{R} \text{ has Field then}

\[ \text{inverse} : \% \to \text{Union}(\%,"failed") \]

Note the conditional definition: the coefficients \( \texttt{R} \) need only be a \texttt{Ring}, but if, in addition, they are a \texttt{Field}, i.e. division is possible, then it makes sense to talk about the inverse of a matrix. Of course, the inverse operation may fail if the matrix is singular, so the return domain of \text{inverse} is defined to be \text{Union}(\%,"failed"). \texttt{MatrixCategory} is not itself a descendant of \texttt{Ring}, because matrices can only be added, multiplied etc. if they conform. However, square matrices do form a ring, and Axiom knows this.

**Convention 10.** The infix binary predicate \texttt{has} can be used to test if domains belong to categories, or if they have specified attributes.

\[ \to \texttt{SquareMatrix}(2,\texttt{Integer}) \texttt{ has Field} \]
\[ \text{(7) true} \]

This implies that a square matrix domain would itself be an acceptable parameter to \texttt{matrix}.

\[ \to [[[[1,2],[3,4]],1,0],[0,[[5,6],[7,8]],1]]::\text{Matrix} \texttt{SquareMatrix}(2,\texttt{Integer}) \]
\[ \text{(8) } \]
\[ \to \text{transpose} \% \]

\[ \to 1+ 2+ +1 0+ +0 0++ \]
\[ 1+3 4+ +0 1+ +0 0+1 \]
\[ 0+ 0+ +5 6+ +1 0+1 \]
\[ 0+0 0+ +7 8+ +0 1++ \]

\[ \text{Type: } \text{Matrix} \texttt{(SquareMatrix}(2,\texttt{Integer})) \]

\[ \to 1+ 2+ +0 0++ \]
\[ 1+3 4+ +0 0+1 \]

\[
\begin{bmatrix}
  1 & 0 \\
  0 & 0 \\
\end{bmatrix}
\]

Type: Matrix(SquareMatrix(2,Integer))

\[
\begin{bmatrix}
  8 & 10 \\
  15 & 23 \\
\end{bmatrix}
\]

Type: Matrix(SquareMatrix(2,Integer))

\[
\begin{bmatrix}
  8 & 10 \\
  15 & 23 \\
\end{bmatrix}
\]

Type: Matrix(SquareMatrix(2,Integer))

This is not necessarily the most stunning application of Axiom, but it does show that the type system can be used to construct some truly amazing objects. We notice also that the type system interpreted some occurrences of 1 and 0 as requiring appropriate matrices as their values, in order to make the command type-consistent.

In practice these extremely complex types are often used in the middle of a calculation, even when the final result is quite simple or straight-forward. Grabmeier\cite{Grab91a} gives an example from genetics, where one of the intermediate objects in his construction belonged to the domain

\begin{verbatim}
List PolynomialIdeals(Fraction Integer,
               DirectProduct(4,NonNegativeInteger),
               [x1,x2,x3,x4],
               DistributedMultivariatePolynomial([x1,x2,x3,x4],
               Fraction Integer))
\end{verbatim}

Convention 11. Every Axiom constructor, i.e. functor or category, has an abbreviation, consisting of at most eight upper-case letters (seven in the case of categories). These serve two purposes: they can be used on input and output in order to make the names of the types shorter, and they denote the directory in which the corresponding Axiom library lives. The defaults for category Cat, with abbreviation CAT, are called Cat\&, with abbreviation CAT-.

For example, the abbreviation for Integer is INT, and the compiled library lives in the directory INT.nrlib. Grabmeier's type can therefore also be written as

\begin{verbatim}
List IDEAL(FRAC INT,DIRPROD(4,NNI),[x1,x2,x3,x4],DMP([x1,x2,x3,x4],FRAC INT)
\end{verbatim}

which is certainly shorter, even though still somewhat of a mouthful.
1.5. CATEGORIES

1.5.1 Using the )display command

Let us begin with a very simple example of the )display command.

-> )d op pop!

There are 4 exposed functions called pop! :

1. `ArrayStack(D1) -> D1 from ArrayStack(D1) if D1 has SETCAT`
2. `Dequeue(D1) -> D1 from Dequeue(D1) if D1 has SETCAT`
3. `D -> D1 from D if D has SKAGG(D1) and D1 has TYPE`
4. `Stack(D1) -> D1 from Stack(D1) if D1 has SETCAT`

Examples of pop! from ArrayStack

```
a: ArrayStack INT:= arrayStack [1,2,3,4,5]
pop! a
a
```

Examples of pop! from Dequeue

```
a: Dequeue INT:= dequeue [1,2,3,4,5]
pop! a
a
```

Examples of pop! from StackAggregate

```
a: Stack INT:= stack [1,2,3,4,5]
pop! a
a
```

Examples of pop! from Stack

```
a: Stack INT:= stack [1,2,3,4,5]
pop! a
a
```

There are 4 exposed functions listed, with their argument types, result type and (following the word from) the source of their implementation: a combination known collectively as a signature. Once one knows that SKAGG is an abbreviation for StackAggregate, which is easy enough to find out

->)d abbrev SKAGG

SKAGG abbreviates category StackAggregate

Axiom functions have a special syntax (a tagged comment) that provides examples of functions from the algebra source code. For example, the `Stack` domain has the `pop!` function.

```
pop_! : % -> S
++ pop! returns the top element of the stack, destructively
++ modifying the stack to remove that element.
++
++X a: Stack INT:= stack [1,2,3,4,5]
++X pop! a
++X a
```

The special form of the ++ comment, which is ++X provides an example of the use of the function. So, in the above output, we see

Examples of pop! from Stack
a:Stack INT:= stack [1,2,3,4,5]
pop! a
a

which shows three commands a user can execute to demonstrate the function

-> a:Stack INT:= stack [1,2,3,4,5]

(1) [1,2,3,4,5] Type: Stack(Integer)
(2) -> pop! a
(2) 1 Type: PositiveInteger
(3) -> a
(3) [2,3,4,5] Type: Stack(Integer)

making it clear that the stack a has been modified.

A more complicated example would be given by \( \int d \) op \textit{integrate}, and we will only explain some of the entries. The Axiom library has 32 exposed integrations and 10 unexposed ones.

\[ [29] \quad D \rightarrow D \text{ from } D \]
\[ \text{if } D \text{ has UPXSCAT}(D1) \text{ and } D1 \text{ has RING and } D1 \text{ has ALGEBRA(FRAC(INT))} \]

\[ [7] \quad \text{(D2,Symbol)} \rightarrow \text{Union(D2,List(D2)) from FunctionSpaceIntegration(D4,D2)} \]
\[ \text{if } D4 \text{ has Join(EuclideanDomain,OrderedSet,CharacteristicZero,RetractableTo(Integer),LinearlyExplicitRingOver(Integer)) and } D2 \text{ has Join(TranscendentalFunctionCategory,PrimitiveFunctionCategory,AlgebraicallyClosedFunctionSpace(D4))} \]

The function [29] is the one we used to integrate the Puiseux series: UPXSCAT is the abbreviation for \textit{UnivariatePuiseuxSeriesCategory}, and \( D1 \), the coefficients of the series, must be an algebra over the rational numbers (otherwise we could not regard the exponents as coefficients, which one has to do when integrating \( x^{p/q} \) to \( \frac{q}{p+q} x^{1+p/q} \)) and a ring.

The function [7] is the one we used for most of the other integrations we have performed so far. Although the signature looks fairly lengthy, we have already analysed the fact that the signature is of the form

\[ \text{(D2,Symbol)} \rightarrow \text{Union(D2,ListD2)} \]

The rest of the lines are merely explaining what properties D2 must have. D4 plays the role of the coefficients in the function being integrated. We always had \textit{Integer} in there, but this is not strictly necessary.

-> 2*cos(4*x)**3::Expression RomanNumeral

3
(1) II cos(IV x) Type: Expression(RomanNumeral)
(2) -> integrate(\%x,x)
\[
\frac{2}{VI}
\]

\[ (\cos(IV \, x) + II)\sin(IV \, x) \]

Type: \text{Union(Expression(RomanNumeral),List(Expression(RomanNumeral)))}

It can clearly be seen that, in Expression \text{RomanNumeral}, the coefficients are indeed members of \text{RomanNumeral}, but the exponents are not.
Chapter 2

How does one program in the Axiom system by James H. Davenport

This is (mostly) quoted verbatim, with permission, from Davenport\cite{Dave92b}.

2.1 Introduction

Axiom can be used in essentially three ways. The first corresponds to the “pocket calculator” style of use – simple commands can be typed and the answer is printed. These commands can be issued from the keyboard in traditional style, or via the Hyperdoc menu system, or through “.input” files, and are handled by what is generally called the “Axiom interpreter”. This interpreter does more than traditional computer algebra systems do, since Axiom is a typed system, and the interpreter has to do type inference.

The second style corresponds to what might be called the “programmable pocket calculator” style, where simple functions are defined, or variables given values for later use. An example of a simple function would be

\[
\text{fac n} == \text{if n < 3 then n else n*fac(n-1)}
\]

as a definition of the factorial function. A slightly more complicated example (take from IBM\cite{IBMx91} and Jenks & Sutor\cite{Jenk92}) goes as follows.

\[
\text{mersenne i} == 2^{**i} - 1
\]

This line defines a function for computing the \(i\)-th Mersenne number

\[
\text{mersenneIndex} := [\text{n for n in 1.. | prime?(mersenne(n))}]
\]

This line, which produces the following output from Axiom,

\begin{verbatim}
(2) [2,3,5,7,13,17,19,31,61,89,...] Type: Stream(PositiveInteger)
\end{verbatim}

computes an infinite (but lazily evaluated) list of the indices of those Mersenne numbers which are actually prime.
mersennePrime n == mersenne mersenneIndex(n)

This defines a function which produces the \( n \)-th Mersenne prime. It can be used as in the following input line (and corresponding output).

\[
\text{mersennePrime 5}
\]

\( (4) \quad 8191 \quad \text{Type: PositiveInteger} \)

In this style, we have various “one-liners” which interact with each other, much as programmed functions on a pocket calculator.

In the third style, we define new complete data types to Axiom. It is this third style of programming that this paper addresses.

## 2.2 Programming concepts

Axiom has several fundamental concepts, which we have to outline briefly.

### Domain

A domain is what many other languages would call an \textit{abstract data type}, i.e. a specification of certain data objects and the operations on them. A typical domain would be \texttt{Integer}, whose elements are the underlying integers of the implementation (infinite precision, of course), and which supports the following operations, as given by the Axiom command \texttt{)show Integer}, or by using the Hyperdoc browser. We remind the reader that \texttt{/*} is Axiom’s notation for the “current domain”, i.e. \texttt{Integer} in this case, and that all operations are prefix unless shown otherwise (e.g. the infix \* and quo).

\texttt{Integer} is a domain constructor

Abbreviation for \texttt{Integer} is \texttt{INT}

This constructor is exposed in this frame.

Issue \texttt{)edit bookvol10.3.pamphlet} to see algebra source code for \texttt{INT}

--- Operations ---

\[
\begin{align*}
\text{\texttt{?*? : (\%,\%) -> \%}} & \\
\text{\texttt{?*? : (NonNegativeInteger,\%) -> \%}} & \\
\text{\texttt{?*? : (\%,\%) -> \%}} & \\
\text{\texttt{?- : \% -> \%}} & \\
\text{\texttt{?< : (\%,\%) -> Boolean}} & \\
\text{\texttt{?> : (\%,\%) -> Boolean}} & \\
\text{\texttt{D : \% -> \%}} & \\
\text{\texttt{OMwrite : (\%,Boolean) -> String}} & \\
\text{\texttt{OMwrite : \% -> String}} & \\
\text{\texttt{1 : () -> \%}} & \\
\text{\texttt{0 : () -> \%}} & \\
\text{\texttt{abs : \% -> \%}} & \\
\text{\texttt{associates? : (\%,\%) -> Boolean}} & \\
\text{\texttt{binomial : (\%,\%) -> \%}} & \\
\text{\texttt{coerce : Integer -> \%}} & \\
\text{\texttt{coerce : \% -> OutputForm}} & \\
\text{\texttt{convert : \% -> Float}} & \\
\text{\texttt{convert : \% -> Pattern(Integer)}} & \\
\text{\texttt{convert : \% -> Integer}} &
\end{align*}
\]
It must be stressed that the use of `)show` or the browser is essential to understanding what is already present in Axiom, and what one has to add to produce a valid domain. If fact, a user cannot write a domain, merely a function (see later) which, when called, will create a domain.
Category  The set of all domains (declared as) belonging to this category, i.e. having the stated operations and associated axioms. For example, the domain \texttt{Integer} belongs to the category \texttt{Ring}, which has the following operations, again given by \texttt{show Ring} or the browser.

\texttt{Ring} is a category constructor
\texttt{Abbreviation for Ring is RING}
This constructor is exposed in this frame.
Issue \texttt{edit bookvol10.2.pamphlet} to see algebra source code for \texttt{RING}

\begin{verbatim}
------------------------------- Operations --------------------------------
?*?: (%,%) -> %    ?*?: (Integer,%)-> %
?*?: (NonNegativeInteger,%)-> %    ?*?: (PositiveInteger,%)-> %
?**?: (%,NonNegativeInteger) -> %    ?**?: (%,PositiveInteger) -> %
?+?: (%,%) -> %    -?: % -> %
-?: % -> %    ?=? : (%,%) -> Boolean
1 : () -> %
?^?: (%,NonNegativeInteger) -> %    ?^?: (%,PositiveInteger) -> %
coerce : Integer -> %    coerce : % -> OutputForm
hash : % -> SingleInteger    latex : % -> String
one? : % -> Boolean    recip : % -> Union(%,"failed")
sample : () -> %    zero? : % -> Boolean
?-?: (%,%) -> Boolean
characteristic : () -> NonNegativeInteger
subtractIfCan : (%,%) -> Union(%,"failed")
\end{verbatim}

Note that 0 and 1 are \textit{nul- lary operations}, since their actual value may well be very different in different domains belonging to the category \texttt{Ring}, e.g. in the ring of \textit{n}-by-\textit{n} square matrices, the 1 is the identity matrix, and not the matrix consisting entirely of 1.

Categories can be parameterized, as in \texttt{Algebra(R)}, where \textit{R} is some \texttt{CommutativeRing}, which gives the category of all algebras over \textit{R}.

Functor  A function which takes arguments which are either individual objects, in which case the domain they come from is specified, or domains, in which case the category they come from is specified, and which returns a domain specified to live in a particular category. For Example:

\texttt{Z=Integer} is the result of applying the function \texttt{Integer} to no arguments;
\texttt{Q} is the result of applying the function \texttt{Fraction} (which requires an \texttt{IntegralDomain} as its argument) to the \texttt{IntegralDomain Integer}. The result is a \texttt{Field}.

\texttt{Z[y]} is the result of applying the functor \texttt{UnivariatePolynomial} to the object \textit{y} (from the domain \texttt{Symbol}) and the domain \texttt{Integer} (from the category \texttt{Ring}). The result is declared to be a \texttt{Ring}, or, more precisely, to belong to the category \texttt{UnivariatePolynomialCategory(R)}, where \textit{R} is the \texttt{Ring} supplied.
2.3. A FIRST PROBLEM – WEIGHTED POLYNOMIALS

**Package** Very like a function, but does not specify a new data object, merely some new functions. A typical example would be `UnivariatePolynomialFunctions2`, which defines the operation

\[
\text{map} : (R \to S, \text{UnivariatePolynomial}(x,R)) \to \text{UnivariatePolynomial}(y,S)
\]

where \(x\) and \(y\) are elements of `Symbol`, and \(R\) and \(S\) belong to the category `Ring`. In mathematical terms, this function takes a function \(\theta\) from \(R\) to \(S\), and performs the corresponding function from \(R[x]\) to \(S[y]\). To get the actual function from \(R[x]\) to \(S[y]\), one would have to use Axiom’s notation for “lambda expressions”, viz. `map(f,#1)`, i.e. that function which, given an element \(p\) of `UnivariatePolynomial(x,R)` computes `map(f,p)`.

**Constructor** The generic term including category, functor, and package.

2.3 A first problem – Weighted Polynomials

2.3.1 The problem definition

Our aim here is to emulate CAMAL’s (Fitch[Fitc74]) handling of “weighted polynomials”, a concept which is also found in Reduce (Hearn[Hear87]) via the commands `weight` and `wtlevel`. For those not familiar with the idea, we give a quick summary here. We will then develop two alternative implementations incrementally. The complete definitions will be given in appendices.

Some of the polynomial variables have a (positive integer) weight associated to them. If \(x\) has weight \(k\), the \(x^n\) has weight \(kn\), and the weight of a monomial is the sum of the weights of the powers in it. This means that the weight of a product of two monomials is the sum of the weights. A certain integer (the weight level) is chosen, and all monomials of weight exceeding this are dropped. If we call this dropping operation \(\lfloor\rfloor\) (by analogy with the rounding of integers), we see that \(\lfloor f + g \rfloor = \lfloor f \rfloor + \lfloor g \rfloor\), and that \(\lfloor fg \rfloor = \lfloor \lfloor f \rfloor \lfloor g \rfloor \rfloor\).

The outline implementation we suggest is conceptually similar to that of Reduce (Hearn[Hear87]). The weight is stored as the exponent of a virtual variable (\(k^*\) in Reduce), and monomials are stored as coefficients of the appropriate power of this variable. Reduce does not ensure that \(k^*\) has to be the most significant variable, in terms of polynomial ordering, and hence the truncation is not as efficient as it might be.

The key Axiom functions that we need to use are briefly explained now.

- **Polynomial** is the type Axiom assigns by default to polynomial-like objects. These types can be seen in Axiom after every object is computed (use the Axiom system command `set message type on` if they are not being shown). This is a functor, which, given a `Ring` \(R\), returns a domain in `PolynomialCategory(R,Symbol,IndexedExponents(Symbol))`, i.e. the variables are the elements of the `Symbol` domain, which corresponds to ordinary symbols, and the exponents are from `IndexedExponents`, which gives a non-negative integer for every symbol (for which it is non-zero). Hence this type is a traditional sparse multivariate polynomial, and is Axiom’s default type. There are others, in particular dense polynomials and polynomials represented in a distributed, rather than recursive, fashion, but these do not appear unless explicitly called for.

- **PolynomialCategory** is the category of the result of `Polynomial`, as is show by the
PolynomialRing is used in the implementation of Polynomial (via SparseMultivariatePolynomial, as can be found by the Lineage option of the browser). This functor takes as arguments a Ring $R$, the ring of coefficients, and an OrderedAbelianMonoid $E$, the set of exponents, and produces formal polynomials. In particular, if $E$ is $\mathbb{N}$ (the domain NonNegativeInteger in Axiom parlance), one gets the standard univariate polynomials, where no name has been given to the variable.

PolynomialRing(R:Ring,E:OrderedAbelianMonoid):=
FiniteAbelianMonoidRing(R,E) with
if R has canonicalUnitNormal then canonicalUnitNormal == FreeModule(R,E) add
Term:= Record(k:E,c:R)
Rep:= List Term
1 == [[0$E,1$R]]
p1,p2: %
if R has EntireRing then
p1 * p2 ==
null p1 => 0
null p2 => 0
p1.first.k = 0 => p1.first.c * p2
ps = 1 => p1
+/[[t1.k+t2.k,t1.c*t2.c]$Term for t2 in p2]
for t1 in reverse(p1)]
-- This 'reverse' is an efficiency improvement:
-- reduces both time and space [Abbot/Bradford/Davenport]
else
p1 * p2 ==
null p1 => 0
null p2 => 0
p1.first.k = 0 => p1.first.c * p2
p2 = 1 => p1
+/[[t1.k+t2.k,r]$Term for t2 in p2 | (r:=t1.c*t2.c) ^= 0]

An OrderedCancellationAbelianMonoid is a cancellation abelian monoid which is also a totally ordered set, such that the ordering is compatible with addition: $x \leq y \Rightarrow x + z \leq y + z$. Since it is a cancellation abelian monoid, i.e. satisfies $x + y = y + z \Rightarrow x = y$, there is a partial subtraction operation: $x - y$ is the unique $z$ such that $z + y = x$, if it exists. An OrderedAbelianMonoidSup is an OrderedCancellationAbelianMonoid in which, in addition, there is an operation $\sup$ with respect to the partial ordering induced by subtraction. In other words $\sup(x, y) - x$ and $\sup(x, y) - y$ exist, and $\sup(x, y)$ is minimal (with respect to $<$) with this property.
2.3. A FIRST PROBLEM – WEIGHTED POLYNOMIALS

for t1 in reverse(p1)]
    -- This 'reverse' is an efficiency improvement:
    -- reduces both time and space [Abbot/Bradford/Davenport]

if R has CommutativeRing then
    p ** nn ==
    null p => 0
    nn = 0 => 1
    p.rest = [] => [[nn * p.first.k, p.first.c ** nn]]
    binomThmExpt([p.first],p.rest,nn)

binomThmExpt(x,y,nn) ==
    nn = 0 => 1
    ans,xn,yn:=%
    bincoef: Integer
    powl: List(%):= [x]
    for i in 2..n repeat powl:=[x * powl.first, :powl]
    yn:=y; ans:=powl.first; i:=1; bincoef:=nn
    for xn in powl.rest repeat
        ans:= bincoef * xn * yn + ans
        bincoef:=(nn-1) * bincoef quo (i+1); i:=i+1
        -- last I and BINCOEF unused
        yn:= y * yn
        ans + yn
    else
        p ** nn == repeatMultExpt(p,nn)

repeatRultExpt(x,nn) ==
    nn = 0 => 1
    y:= x
    for i in 2..nn repeat y:= x * y
    y

The returned domain belongs to the category FiniteAbelianMonoidRing, with the additional property canonicalUnitNormal (see Davenport & Trager [Dave90] for an explanation of this property) if the ground ring R has this property. The implementation is to take FreeModule(R,E), and to add (hence the use of this keyword) certain additional operations – we have just quoted the definition of the unit and multiplication, in fact there are more. We find it convenient to work in terms of the internal representation of FreeModule, hence the Rep line (which in turn relies on the definition of Term). We will see further examples of this methodology later on, as method (4) for the definition of Axiom functors.

2.3.2 The problem specification

Proceeding in a top-down fashion, we can see that we are going to need a construction which takes as arguments a Ring R, some weights for some symbols, and an initial weight level. This will return a Ring as result, the ring of weighted polynomials, in the named symbols

---

2 An “abelian monoid ring” bears the obvious relationship to a “group ring”: viz. it is the set of formal sums of ring elements, indexed by elements of the abelian monoid, with addition etc. being defined component-wise, and multiplication making use of the addition of abelian monoid indices. The use of the word “finite” here is to indicate that we consider only finite sums, i.e. the ring element is zero for all but finitely many elements of the abelian monoid.
(at least), over $R$, with the weight level as specified. At this point, certain design decisions need to be made.

- Should the weight level be changeable? In Reduce, it is, and advice from the theory of repeated approximation (see, for example, Barton & Fitch[Bart72]) led us to believe that the weight level should be changeable.

- Should the weights themselves be changeable? In Reduce, they are not, and making them changeable would require the re-computation of the weights of all products. Of course, the user of Axiom is free to build two different domains with different weights assigned in each, a flexibility that is not possible in Reduce, and we believe that this should be sufficient.

- How should the weights be represented. We could produce a separate Axiom data type, we could accept them as equations, and insist at run time that they be of the form “symbol=non-negative integer”, or we could treat them as a list of symbols and a corresponding list of non-negative integers. For simplicity, we chose the last as the user interface (but see later for the internal handling).

- Should the weighted polynomials contain only the symbols specified in the weight list, or others? This is debatable, but it seemed simpler, as the implementation progressed, to allow other symbols, which then effectively have a weight of 0.

We can now probably write the specification part of this functor.

```plaintext
)abbrev domain OWP OrdinaryWeightedPolynomials

OrdinaryWeightedPolynomials(R:RIng,  
  vl:List Symbol, 
  wl:List NonNegativeInteger, 
  wtlevel:NonNegativeInteger):

Ring with

  if R has CommutativeRing then Algebra(R)

  coerce : % -> Polynomial(R) 
     ++ coerce will convert back into a Polynomial(R), ignoring weights

  coerce : Polynomial(R) -> % 
     ++ coerce a Polynomial(R) into Weighted form, 
     ++ applying weights and ignoring terms

  if R has Field then 

    "/" : (%,%) -> Union(%,"failed") 
     ++ a / b, the division only works if minimum weight 
     ++ of divisor is zero, and if R is a Field

  changeWeightLevel : NonNegativeInteger -> Void 
     ++ changeWeightLevel changes the weight level to the new value given: 
     ++ NB: previously calculated terms are not affected
```

The `)abbrev` line is necessary for the definition of any functor, since the abbreviation (up to eight letters, or seven for a category) defines, among other things, the name of the directory in which the compiled code will be stored.
2.3. A FIRST PROBLEM – WEIGHTED POLYNOMIALS

Axiom comments begin with either -- or ++. The former fulfil the traditional role of commenting programs. The latter, which can only appear in the appropriate contexts, are picked out by the program that builds the HyperDoc database, and can be retrieved by HyperDoc when it comes to describing operations (as in the case of the \texttt{changeWeightLevel} operation quoted above) or the whole constructors.

Axiom checks the first word of ++ comments on functions to see that it is the name of the function. If not, it complains.

In general, there should be examples given for every function, using the ++ X syntax. Comment lines starting with these three characters are displayed as help text when the user asks about a function with \texttt{display operation}.

We could now start implementing this data type, but a thought crosses our mind. While \texttt{Polynomial} is Axiom’s default representation, it is not the only one, and it would be a pity for this “weighted polynomial” facility not to be available for other implementations as well. Hence we decide that we will implement \texttt{OrdinaryWeightedPolynomials} in terms of a more general constructor, which takes the polynomial type as an argument. This leads to the following implementation for the body of \texttt{OrdinaryWeightedPolynomials}.

\begin{verbatim}
== WeightedPolynomials(R,Symbol,IndexedExponents(Symbol),
   Polynomial(R),vl,wl,wtlevel)

This is essentially and \texttt{add} form in which nothing is being added: the operations of \texttt{OrdinaryWeightedPolynomials} will be precisely those of \texttt{WeightedPolynomials}.

The header of \texttt{WeightedPolynomials} now practically writes itself.
\end{verbatim}

\begin{verbatim}
)abbrev domain WP WeightedPolynomials
WeightedPolynomials(R:RIng,VarSet: OrderedSet, E:OrderedAbelianMonoidSup,
P:PolynomialCategory(R,E,Varset),
vl:List Varset, wl:List NonNegativeInteger,
wtlevel:NonNegativeInteger):

Ring with
  if R has CommutativeRing then Algebra(R)
  coerce : % -> P
    \texttt{++ coercer convers back into a "P", ignoring weights}
  if R has Field then
    "/": (%,%) -> Union(%,"failed")
    \texttt{++ a / b division only works if minimum weight}
    \texttt{++ of divisor is zero, and if R is a Field}
    coerce : P -> %
    \texttt{++ coercer a "P" into Weighted form, applying weights and ignoring terms}
  \texttt{changeWeightLevel : NonNegativeInteger -> Void}
    \texttt{++ changeWeightLevel changes the weight level to the new value given:}
    \texttt{++ NB: previously calculated terms are not affected}

How are we going to implement this type? There are various possibilities for implementing a functor in Axiom.

(1) Direct re-use of another domain, as
\end{verbatim}
OrdinaryWeightedPolynomials re-uses WeightedPolynomials

(2) An existing domain with new operators added by means of an add clause. The previous method can be viewed as a trivial case of this method.

(3) A new implementation, where the representation of the data objects is defined, but all operations are defined from scratch (or provided by the default definitions given in certain categories)

(4) A hybrid approach, where a domain is added to, but we also quote its representation in order to dive into its internals. This is quite common (see, for example, the definition of PolynomialRing in terms of FreeModule), but also the most dangerous, as the domain to which one adds is no longer being treated as a “black box”, but rather as something one can dive into at will. Any changes in the representation of the domain being added to can invalidate the new domain being built.

2.3.3 The problem implementation

Let us first try the third method, where we use PolynomialRing as our representation. The essentials of our implementation will then look as follows (the details of coerce (p36) etc. will be discussed later).

Rep := PolynomialRing(P,NonNegativeInteger)

w,x1,x2:%

0 == 0$Rep

1 == 1$Rep

x1 = x2 ==  
-- Note that we must strip out any terms greater than wtlevel  
while degree x1 > wtlevel repeat  
x1 := reductum x1  
while degree x2 > wtlevel repeat  
x2 := reductum x2  
x1 =$Rep x2

x1 + x2 == x1 +$Rep x2

-x1 == -$Rep x1

x1 * x2 ==  
-- Note that this is probalby an extremely inefficient definition  
w:=x1 * $Rep x2  
while degree(w) > wtlevel repeat  
w:=reductum w  
w

One important point that crops up here is the necessity to distinguish the operations of the representation (PolynomialRing) from those of the type being defined. Since elements can be viewed as belonging to either the data type or its representation, there is a potential for ambiguity, when the data type and the representation have operations of the same signature. In this case, the unqualified operation name will refer to that of the data type, and that of the representation has to be obtained by use of the $Rep syntax – meaning use the operation
2.3. A FIRST PROBLEM – WEIGHTED POLYNOMIALS

from the data type Rep. A trivial example of the definition of + given above, which can be paraphrased in English as “to add two elements of WeightedPolynomials, add them as if they were elements of the representation, i.e. elements of PolynomialRing.” Slightly more complicated is the definition of equality, which can be paraphrased in English as “to test two elements of WeightedPolynomials for equality, first remove any terms of weight greater than the current weight level, then test them for equality as elements of the representation, i.e. elements of PolynomialRing”. It is perhaps worth noting that a side-effect of this is that calls to changeWeightLevel can affect the result of equality tests.

The reader may well say “Ring was meant to define many more operations than you have done there – where are the rest?” The answer is that these are provided by the defaulting operations in the various categories. For example, the first operation we have not defined is the multiplication operation with signature "*: (Integer,%) -> %". This is acquired by default from the category AbelianGroup, an ancestor of Ring, where the operation is defined by

```
AbelianGroup() : Category == SIG where

SIG ==> CancellationAbelianMonoid with

"*" : (Integer,%) -> %
++ n*x is the product of x by the integer n.
```

2.3.4 The PolynomialRing implementation

Here we use PolynomialRing as our base type, as well as our representation, in what corresponds to method (4) of the choice outlined earlier. Again, we have left the various definitions of coerce (p36) etc. for later consideration: we focus here on the differences between this implementation and the previous one.

```
== PolynomialRing(P,NonNegativeInteger)
add
--representations
Term := Record(k:NonNegativeInteger,c:P)
Rep := List Term
w,x1,x2:%
x1 * x2 ==
  null x1 => 0
  null x2 => 0
  r:P
  x1.first.k = 0 =>
    [[t2.k,r]$Term for t2 in x2 | (r:=x1.first.c * t2.c) ^= 0]
x2 = 1 => x1
+/[[[n,r]$Term for t2 in x2 | (n:=t1.k+t2.k) <= wtlevel and
                     (r:=t1.c*t2.c) ^= 0]
   for t1 in reverse(x1)]
  -- This 'reverse' is an efficiency improvement:
  -- reduces both time and space [Abbott/Bradford/Davenport]
import RepeatedSquaring(%)
x:% ** n:NonNegativeInteger ==
```
We still need a definition of equality, since the definition from \texttt{PolynomialRing} is not adequate, as it does not take account of the current value of the weight level. While the algorithm is very similar, the implementation has to be in terms of the newly-defined \texttt{Rep}, which is a list of terms. Hence \texttt{degree(x1)} is replaced by \texttt{x1.first.k}. Similarly, the construction \texttt{*\$Rep} does not work, since the \texttt{Rep} is now just a list of objects, and has to be replaced by an explicit copy of the definition of equality from \texttt{PolynomialRing}, which is in fact inherited from \texttt{IndexedDirectProductAbelianGroup}.

We no longer need definitions of 0 and 1, which are picked up from \texttt{PolynomialRing}, nor definitions of addition and subtraction. We do, however, need a definition of multiplication, since the definition in \texttt{PolynomialRing} does not drop terms greater than the weight level. This definition is based on that given earlier for multiplication in \texttt{PolynomialRing}.

In addition, we now need a definition of exponentiation. The reason for this is related to one of the major stumbling-blocks people find when programming in Axiom, so we shall analyse it carefully. We have already said that it is not necessary to provide all the definitions required for a data type, as they could be picked up from defaulting packages. When methodologies (2) or (4) are used, there are in fact two places where such missing definitions could be picked up from: the defaulting packages or the so-called \texttt{add} chain — the functor which is quoted in the \texttt{add} clause, or, recursively, the functor which is quoted in its \texttt{add} clause, and so on. Which should we use? The rule in Axiom is quite simple, though its implications are profound.

\textbf{Principle 9: A function is first searched for in the implementation of a given functor, then recursively up the \texttt{add} chain, without examining defaulting packages. If this fails to find a definition, then the defaulting packages are searched, from most specific to most general.}

The implications of this rule for exponentiation are as follows.

(i) There is a default definition of exponentiation in \texttt{Monoid}, and hence in \texttt{Ring}, which works by repeated squaring. This definition would be perfectly adequate for our use (using multiplication we have just defined in \texttt{WeightedPolynomials})

(ii) There are other definitions of exponentiation in \texttt{PolynomialRing}, as we have seen earlier, which use the binomial theorem if the coefficient ring is commutative, and a repeated multiplication algorithm otherwise.

(iii) Therefore, by the rule quoted above, it is one of the definitions in (ii) which will be used. Hence, they will use the definition of multiplication defined in \texttt{PolynomialRing}, and so will not take advantage of the weight level.

Hence, in order to get a satisfactory implementation of exponentiation, we need to repeat the defaulting definition, or provide some definition that will use the multiplication of \texttt{WeightedPolynomials}.

A related issue comes up in the definitions of \texttt{zero?} and \texttt{one?}. These are defined, in \texttt{AbelianMonoid} and \texttt{Monoid} respectively, to have defaulting definitions \texttt{zero? \ x \ == \ x=0} and \texttt{one? \ x \ == \ x=1}. Since these definitions happen not to be over-ridden in the \texttt{add} chain, they are the definitions that apply in \texttt{WeightedPolynomials}, and so use \texttt{WeightedPolynomials'} definition of equality.

\textit{However}, were a later author of \texttt{PolynomialRing} to add other definitions, these would be picked up instead.
### 2.3.5 Miscellaneous definitions

Here we give some miscellaneous definitions that should form part of the implementation of `WeightedPolynomials`. The first three lines deal with the definition of `changeWeightLevel`.

```plaintext
n:NonNegativeInteger

changeWeightLevel(n) ==
  wtlevel:=n
```

We had earlier decide to represent the weights by a list of variables and a corresponding list of weights, but this is rather clumsy for internal manipulation. Hence the next few lines define an internal data structure called `lookupList`, initialize it, and provide a local function (i.e. one not usable outside the body of the functor) for looking up the weight attached to a particular variable.

```plaintext
lookupList: List Record(var:VarSet, weight:NonNegativeInteger)

if #vl ^= #wl then error "incompatible length lists in WeightedPolynomial"

lookupList:=[[v,n] for v in vl for n in wl]

lookup:VarSet -> NonNegativeInteger
lookup v ==
  l:=lookupList
  while l ^= [] repeat
    v = l.first.var => return l.first.weight
    l:=l.rest
  0
```

We now have to have some method of creating elements of the domain `WeightedPolynomials`. The obvious way is to provide a coercion operator from `P` (which in the case of `OrdinaryWeightedPolynomials` will be the usual type `Polynomial` of Axiom) to `WeightedPolynomials`. This is the function of the next few lines. `coerce` itself is simple: it just calls `innercoerce`, passing it the weight level. `innercoerce` recursively deconstructs the input polynomial, decreasing the weight level as appropriate.

```plaintext
p:P
z:Integer

innercoerce:(p,z) -> %
innercoerc(p,z) ==
  z < 0 => 0
  zero? p => 0
  mv:= mainVariable p
  mv case "failed" => [[0,p]]
  n:=lookup(mv)
  up:=univariate(p,mv)
  ans:%
  ans:=0
  while not zero? up repeat
    d:=degree up
    f:=n*d
    lcup:=leadingCoefficient up
    up:=up-leadingMonomial up
    mon:=monomial(1,mv,d)
```
2.4 A second problem – FourierSeries

2.4.1 The problem definition

Our aim here is to implement an equivalent of CAMAL's (Fitch[Fitch74]) handling of truncated Fourier series. We have some domain of “angles” – in CAMAL's case linear combinations with integer coefficients (lying in the range \(-63 \ldots 63\)) of the eight angular variables \(s, \ldots, z\). We can build \(\sin\) or \(\cos\) of these variables, and use them as coefficients in polynomial expressions, where products of trigonometric functions are always linearised. There are more operations provided in CAMAL, e.g. integration with respect to an angular variable, but we will not bother with these for simplicity of exposition.

Within CAMAL, the coefficients of expressions in these trigonometric functions will therefore not involve other trigonometric functions, but will involved weighted polynomials. These we have already defined, and there seems no absolute need to use weighted polynomials, though they are in practice the most common type of coefficient required. However, we probably need to assume that the coefficients commute with each other and with the trigonometric terms, since otherwise the linearisation of products is not well-defined. Furthermore, since

\[
\sin(A) \sin(B) = \frac{\cos(A - B) - \cos(A + B)}{2}
\]

we must be able to divide by two. For simplicity, therefore, we insist on the ability to divide by any non-zero integer, i.e. that the coefficients should be an Algebra over \(\mathbb{Q}\), the Axiom type \(\text{Fraction Integer}\).

2.4.2 The problem specification

The header of our type Fourier Series now nearly writes itself. The arguments of the trigonometric functions had better be an ordered set, so that we can order the various trigonometric functions, and an abelian group so that the addition and subtraction rules can take place.
It would therefore be possible to require that the domain of these arguments should be an \texttt{OrderedAbelianGroup}, but this may be too strong, and we will restrict ourselves to insisting on \texttt{Join(OrderedSet,AbelianGroup)}\textsuperscript{3}

\begin{verbatim}
FourierSeries(R:Join(CommutativeRing,Algebra(Fraction Integer)),
    E:Join(OrderedSet,AbelianGroup)):
  Algebra(R) with
    if E has canonical and R has canonical then canonical
      coerce : R -> %
        ++ coerce convers coefficients into Fourier Series
    coerce : FourierCompoents(E) -> %
        ++ coerce converts sin/cos terms into Fourier Series
    makeSin : (E,R) -> %
        ++ makeSin makes a sin expression with given argument and coefficient
    makeCos : (E,R) -> %
        ++ makeCos makes a cos expression with given argument and coefficient
\end{verbatim}

The operations here (with the exception of the last \texttt{coerce} (p39), will be explained in the next section, are pretty obvious. What about the line containing the word \texttt{"canonical"}?

Axiom’s definition of the attribute \texttt{canonical} is that a domain is canonical if mathematical equality implies equality of data structure. In particular, it authorises the use of hash-based techniques. There is a discussion in Davenport & Trager\cite{Dave90} and more detail is available in Davenport et al.\cite{Dave88}. In our case, we are saying that, if the coefficients and arguments are canonical, then the data type returned will also be.

The obvious implementation of this is via some kind of \texttt{FreeModule}, using \texttt{R} as the coefficients and the trigonometric functions as the indices. However, we first need to define the trigonometric functions themselves, and this is the purpose of the next section. We will return to the type \texttt{FourierSeries} in the section following.

### 2.4.3 The FourierComponent implementation

It would be possible to use Axiom’s general-purpose type \texttt{Expression} to represent trigonometric functions, but we settled, for pedagogic reasons and partly to keep our code reasonably self-contained, on a separate data type.

The requirements on this data type are quite straight-forward. It should provide ways of making sin and cos functions, and the result should be an \texttt{OrderedSet} so that it can be passed to \texttt{FreeModule}. The header is then equally straight-forward.

\begin{verbatim}
FourierComponent(E:OrderedSet):
  OrderedSet with
    sin : E -> %
        ++ sin makes a sin kernel for use in Fourier series
\end{verbatim}

\textsuperscript{3} An \texttt{OrderedAbelianGroup} would also have the property that \(a < b \Rightarrow a + c < b + c\), but we probably do not need this.
CHAPTER 2. HOW DOES ONE PROGRAM IN THE AXIOM SYSTEM BY JAMES H. DAVENPORT

\[ \cos : E \rightarrow \% \]
\[ ++ \cos \text{ makes a cos kernel for use in Fourier series} \]

\[ \sin? : \% \rightarrow \text{Boolean} \]
\[ ++ \sin? \text{ is true if term is a sin, otherwise false} \]

\[ \text{argument} : \% \rightarrow E \]
\[ ++ \text{argument returns the argument of a given sin/cos expression} \]

Here method (3) seems an appropriate way of defining the data type – all we need store is the argument and a flag indicating whether we have a sin or cos expression. The first part of the implementation is trivial.

\text{add}

```
--representations
Rep:=Record(SinIfTrue:Boolean, arg:E)
e:E
x,y:%

\sin e == [true,e]
\cos e == [false,e]
\sin? x == x.SinIfTrue
\text{argument} x == x.arg
```

The harder question is the order to be imposed on \texttt{FourierComponent}. We have chosen, for no very good reason, to use the order of the arguments, and break ties by sorting \cos a as less than \sin a. Clearly this definition could be adapted to any other strategy.

\[ x < y == \]
\[ x.arg < y.arg \Rightarrow \text{true} \]
\[ y.arg < x.arg \Rightarrow \text{false} \]
\[ x.SinIfTrue \Rightarrow \text{false} \]
\[ y.SinIfTrue \]

The last task of this method of printing the results – again this is achieved by means of a conversion to \texttt{OutputForm}. We have used the constructor \texttt{bracket}, which places the argument in square brackets, in order to distinguish these elements from the ordinary \texttt{Expression} constructions of Axiom.

\texttt{coerce(x):OutputForm ==}

```
hconcat((if x.SinIfTrue then "sin" else "cos")::OutputForm,
bracket((x.arg)::OutputForm))
```

2.4.4 The FourierSeries implementation

Now that we have \texttt{FourierComponent}, we can define \texttt{FourierSeries}. We chose again to use method (4), basing the definition on \texttt{FreeModule(R,FourierComponent(E))}. Hence the start of the definition looks as follows.

\texttt{== FreeModule(R,FourierComponent(E)) add}

```
-- representations
```
2.4. A SECOND PROBLEM – FOURIERSERIES

Term := Record(k:FourierComponent(E),c:R)
Rep := List Term
multiply : (Term,Term) -> %
w,x1,x2 : %
t1,t2 : Term
n : NonNegativeInteger
z : Integer
e : FourierComponent(E)
a : E
r : R

multiply (p39) is a local function, to be defined later, which will multiply two terms. The result may well not be a single term, due to linearisation, but is an element of the FourierSeries domain. We know that \( \cos 0 = 1 \) and \( \sin 0 = 0 \). Furthermore, in order to ensure the ‘‘canonical’’ part, we must be careful about trigonometric functions with negative arguments (the concept of ‘‘negative’’ makes sense: an element is negative if it is less than 0). The following definitions help implement this policy.

1 == [[cos 0,1]]

coerce e ==
sin? e and zero? argument e => 0
if argument e < 0 then
  not sin? e => e:=cos(- argument e)
  return [[sin(- argument e),-1]]
[[e,1]]

makeCos(a,r) ==
a < 0 => [[cos(-a),r]]
[[cos a,r]]

makeSin(a,r) ==
zero? a => []
a < 0 => [[sin(-a),-r]]
[[sin a,r]]

The operations of addition and subtraction, as well as multiplication by elements of \( R \), are all well-inherited from FreeModule. We do however have to define multiplication of two Fourier series, and this is done below.

multiply(t1,t2) ==
r:=(t1.c*t2.c)*(1/2)
s1:=argument t1.k
s2:=argument t2.k
sum:=s1+s2
diff:=s1-s2
sin? t1.k =>
sin? t2.k =>
  makeCos(diff,r)+makeCos(sum,-r)
  makeSin(sum,r) + makeSin(diff,r)
sin? t2.k =>
  makeSin(sum,r) + makeSin(diff,r)
makeCos(diff,r) + makeCos(sum,r)
x1+x2 ==
  null x1 => 0
  null x2 => 0
  +/[+[multiply(t1, t2) for t2 in x2] for t1 in x1]
Chapter 3

Axiom and Category Theory

3.1 Covariance and Contravariance

Axiom has an order relation between types. The types can be in one of five possible relationships.

A type can be more general than another type. For example, Integer is more general than PositiveInteger.

A type can be more specific than another type. Conversely PositiveInteger is more specific than Integer.

A type can be equal to another type.

A type can be converted or coerced to another type. For example, Fraction(Polynomial(Integer)) can be coerced to Polynomial(Fraction(Integer)).

A type can be unrelated to another type. String and Expression are not related.

Covariance is converting from a wider type to a narrower type. For instance, converting from Matrix(Float) to Matrix(Integer).

Contravariance is converting from a narrower type to a wider type. For instance, converting from Matrix(Integer) to Matrix(Float).

Invariance means that one type cannot convert to another. For instance, a Matrix(Float) which contains numbers which cannot be represented as Integers cannot be converted to a Matrix(Integer).

These facts form an order relation, which by definition is reflexive, transitive and antisymmetric.

Reflexive means that Integer = Integer.

Transitive means that PositiveInteger < Integer < Float implies that PositiveInteger < Float.

Antisymmetric means that PositiveInteger < Float implies not(Float < PositiveInteger).
3.2 Axiom Type Lattice

The types in Axiom form a lattice based on the order relationship. It is a lattice because Axiom supports multiple inheritance.

3.3 Terms to Understand

Suppose we wish to join Complex with Polynomial(Integer). What would elements of this combination look like?
The union of the two is a co-product of topological spaces.
The simple combination is not simply adding elements since
\[ i + x^2 \]
is not a valid combination.
We need the algebraic co-product, known as the tensor product. We end up with a domain of Complex(Polynomial(Integer)).

\[ \rightarrow a: \text{Complex(POLY(INT))} := \text{\%i+3\*x} \]
\[ 3x + \text{\%i} \]
\[ \text{Type: Complex(Polynomial(Integer))} \]

\[ \rightarrow a: \text{POLY(COMPLEX(INT))} \]
\[ 3x + \text{\%i} \]
\[ \text{Type: Polynomial(Complex(Integer))} \]
3.4 Category Definition

A category has four parts. We need a set of objects, usually represented as dots. We need a set of arrows (maps, morphisms), from dot to dot. We need a way to compose arrows in an associative manner. We need an identity arrow from a dot to itself.

The set of all arrows from dot A to dot B is written as $\text{Hom}_C(A, B)$ or, sometimes $C(A, B)$. Notice that the set $C(A, B)$ is disjoint from $C(A, D)$ since each arrow has a unique domain and co-domain.

For the example of the category Set, the objects are sets and the arrows are functions between sets. For the category Ring, the objects are rings and the arrows are ring homomorphisms. Similarly for the category Group, the dots are groups and the arrows are group homomorphisms. For a fixed Ring $R$, the category $R$-Mod has dots which are left $R$-modules and the arrows are $R$-module homomorphisms. We can also look at the category $\text{Mod-R}$ which has dots of right $R$-modules and arrows which are $R$-module homomorphisms. For the category $K$, if $K$ is a field, the dots are $K$-vector spaces and the arrows are $K$-linear transformations.

In Axiom the dots are Types (such as Integer or Character) and the arrows are functions between them with signature:

$$f : \text{Integer} \to \text{Character}$$

Relations between categories is called a functor. A functor $F$ takes things in category $C$ into things in category $D$. We need a function on objects which maps objects of $C$ to objects of $D$. We need a function on arrows which take arrows of $C$ to arrows of $D$.

The categories $C$ and $D$ well defined structure. They have a domain and co-domain of arrows. They have identity arrows. There is a rule of composition of arrows. These form commutative diagrams.

First we have to make sure the functor $F$ maintains the domain and co-domain structure of $C$. When we apply functor $F$ to $C$ we need to preserve all of the structure so $F$ has to be defined on all of these properties. If we look at two dots in category $C$ and a function $f$ which is an arrow in $C$

$$f : A \to B$$

then the functor $F$ has to operate on everything so we get:

$$Ff : FA \to FB$$

This means that if $\text{dom}$ is the domain function in $C$ then the functor $F$ commutes with $\text{dom}$. That is, applying $F(\text{dom}(f)) = \text{dom}(F(f))$.

Next we have to make sure the functor $F$ maintains the identity arrow of $C$. From the above we know that $F(\text{identity}(x)) = \text{identity}(F(x))$.

Finally we have to make sure that the rule for composition of arrows in $C$ is preserved. So the functor $F$ has to make sure that what composes in $C$ also composes with the same diagram in $D$.

Some standard functors are the identity functor $1_C$ which just maps $C$ to $C$. We can form a functor which forgets properties so that the category Group could map
to its underlying set. We can lift a category by forgetting properties, for example, lifting the category of Abelian Group $C$ to Group $D$ by ‘‘forgetting’’ the commutative property of $C$. Similarly the category Ring or the category Module can be mapped to the underlying Abelian Group. There is also the Constant functor which maps all of the dots in $C$ to a single dot in $D$ and all of the arrows in $C$ to the identity arrow in $D$.

The category CommutativeRing $R$ can be mapped to a Group with the functor $GL_n$ which is the group of invertible $N \times N$ matrices with entries in the CommutativeRing $R$.

### 3.5 Monoids and Groups

Given a single element set and a set of arrows from that element to itself we know from the associative property that $(fg)h = f(gh)$ and from the identity property that $ef = f = fe$.

A 1-object category is a monoid. A 1-object category where all of the arrows are invertible is a group.

If we restrict the category so there is at most one arrow between any two objects in the set then we have an ordered set.

A functor $F$ from category $C$ to category $D$ consists of

- object function takes objects of $C$ to objects of $D$
- arrow function takes arrows of $C$ to arrows of $D$

Structurally we have 3 things to preserve.

- domains and co-domains of arrows. In order to preserve structure the functor $F$ has to commute with the domain and co-domain functions. That is, $F(\text{dom}(f)) = \text{dom}(F(f))$ and $F(\text{co-dom}(f)) = \text{co-dom}(F(f))$.
- identity arrows. The functor $F$ must preserve identity so $F(id(x)) = id(F(x))$.
- composition properties of arrows. The functor $F$ must take commuting diagrams to commuting diagrams.
Chapter 4

Axiom Implementation Details

4.1 Makefile

This book is actually a literate program\cite{Knut92} and can contain executable source code. In particular, the Makefile for this book is part of the source of the book and is included below.
Chapter 5

Writing Spad Code

5.1 The Description: label and the )describe command

The describe command will print out the comments associated with Axiom source code elements. For the category, domain, and package sections the text is taken from the Description: keyword.

This information is stored in a database and can be queried with

```lisp
)lisp (getdatabase '|Integer| 'documentation)
```

for the Integer domain. However, this information has other uses in the system so it contains tags and control information. Most tags are removed by the describe function since the output is intended to be displayed in ASCII on the terminal.

The Description: keyword is in the comment block just after the abbreviation command. It is freeform and the paragraph will be reflowed automatically to allow for about 60 characters per line, adjusted for spaces. The Description: section should be written after the keyword in the "++" comments as in:

```spad
)abbrev package D03AGNT d03AgentsPackage
++ Description:
++ This package does some interesting stuff. We can write multiple
++ lines but they should all line up with the first character of
++ the Description keyword. Special \spad{terms} will be removed.
++
++ The above line will force a newline. So will ending a line with \br
++ \tab{5}This will allow primitive formatting\br
++ \tab{5}So you can align text\br
++ \tab{10}Start in column 11\tab{5}and skip 5 spaces\br
++ \tab{10}End in column 11\tab{7}and count out the needed spaces\br
++ \tab{5}note that the last line will not need the \br command
```

As the comment says, the Description should all be aligned under the "D" in Description. You can indent using \tab{n} which will insert \n spaces. You can force a newline in two ways. Either include a blank line (with the "++" comments) or use the \br keyword.

Due to lousy parsing algorithms for comments there are various ways this can all go wrong.
There should not be any macros between the Description: section and the beginning of the definition. This is wrong. It will cause the

```spad
)describe package d03AgentsPackage
to give the wrong output because it does not find the end of the description section properly.
)
abbrev package D03AGNT d03AgentsPackage
++ Description:
++ This description does not work
LEDF ==> List Expression DoubleFloat

d03AgentsPackage(): E == I where
In the Description: section the \tab{nn} function will be transformed into nn spaces. If you end each line with a \br you can control alignment.

++ Description:
++ This is an example of a table alignment
++ \tab{5}First Item \tab{5} This will line up with the following line
++ \tab{5}Second Item \tab{4} This will line up with the following line
++ \tab{5}Third Item \tab{5} This will line up with the following line
If the main body of the category, domain, or package begins with properties rather than functions the Description will be incorrectly recorded. This is a known bug finding the end of the Description section. For instance, this

++ Description:
++ The category of Lie Algebras.
++ It is used by the domains of non-commutative algebra,
++ LiePolynomial and XPBWPolynomial.

LieAlgebra(R: CommutativeRing): Category == Module(R) with
NullSquare
  ++ \axiom{NullSquare} means \axiom{[x,x] = 0} holds.
JacobiIdentity
  ++ \axiom{JacobiIdentity} means that
  ++ \axiom{[x,[y,z]]+[y,[z,x]]+[z,[x,y]] = 0} holds.
construct: ($,$) -> $
  ++ \axiom{construct(x,y)} returns the Lie bracket of \axiom{x}
  ++ and \axiom{y}.
will give the output
{JacobiIdentity} means that} [x,[y,z]]+[y,[z,x]]+[z,[x,y]] = 0 holds.
but reordering it to read:

++ Description:
++ The category of Lie Algebras.
++ It is used by the domains of non-commutative algebra,
++ LiePolynomial and XPBWPolynomial.

LieAlgebra(R: CommutativeRing): Category == Module(R) with
construct: ($,$) -> $
  ++ \axiom{construct(x,y)} returns the Lie bracket of \axiom{x}
  ++ and \axiom{y}.
NullSquare
++ \texttt{\textbackslash axiom\{NullSquare\}} means that \texttt{\textbackslash axiom\{[x,x] = 0\}} holds.
++ \texttt{\textbackslash axiom\{JacobiIdentity\}} means that
++ \texttt{\textbackslash axiom\{[x,[y,z]]+[y,[z,x]]+[z,[x,y]] = 0\}} holds.

will give the output

The category of Lie Algebras. It is used by the domains of non-commutative algebra, LiePolynomial and XPBWPolynomial.

which is correct.
Chapter 6

Writing test cases
Appendix A

The Principles of Axiom

**Principle 1.** AXIOM has an interpreter for interactive use, much like any other system, and a compiler for creating new user-defined data types. The compiler emphasises strict type-checking, whilst the interpreter is more oriented towards ease of use.

**Principle 2.** Every internal Axiom data object belongs to one and only one domain.

**Principle 3.** Values can freely move from sub-domains to larger ones, and, in the interpreter only, in the other direction, provided that this conversion is legitimate.

**Principle 4.** The interpreter is responsible for performing any chain of coercions necessary to understand the user’s intentions, or when required to do so by an explicit use of ::. The compiler will perform a chain of coercions when instructed to do so by the :: operator in compiled code.

**Principle 5.** Any set of Axiom domains \(D_1, \ldots, D_n\) can be combined into a (disjoint) union domain, denoted \(\text{Union}(D_1, \ldots, D_n)\). The \(D_i\) are called the **branches** of the union. The operations available on this union domain are:

- equality – two elements are equal if they come from the same branch and are equal in that branch;
- coercion to OutputForm;
- coercion from each \(D_i\) to the union domain;
- coercion to each \(D_i\) from the union domain, which may fail if the union object is not in the correct branch;
- an `in x` predicate case, for testing if the union object actually is in a particular branch or not.

These union domains correspond to what some other languages call “sum types”. A particularly useful case is exemplified by the “exact quotient” operation on Integer: its return type is \(\text{Union(Integer, "failed"})\), where the special token `failed` is returned if the division is not exact.

**Principle 6.** The Axiom library declares a family of second-order types, known as **categories**. The categories are arranged in a directed acyclic graph, and each domain belong to a specific category, and to all the ancestors of that category. The specification of a category includes...
• all its direct ancestors,
• any additional operations that this category supports, and
• any additional axioms that the operations must satisfy.

The operation \texttt{Join} is used to construct new categories.

\textbf{Principle 7.} Categories can introduce \textbf{default definitions} of operations, which will take effect in any domain belonging to that category unless overridden by a definition in that domain, or in a more specific category.

\textbf{Principle 8.} The functors of Axiom are strongly typed: each parameter which is an Axiom object is specified to come from a particular domain; each parameter which is an Axiom domain is specified to belong to a particular Axiom category. Similarly, the domain returned by a particular functor is specified to belong to a particular category. All construction of domains must satisfy these constraints on the functors.

\textbf{Principle 9.} A function is first searched for in the implementation of a given functor, then recursively up the \texttt{add} chain, without examining defaulting packages. If this fails to find a definition, then the defaulting packages are searched, from most specific to most general.
Appendix B

The Axiom Conventions

Convention 1. Juxtaposition corresponds to (unary) function application.

Convention 2 (borrowed from APL). All system commands, i.e. those that do not perform, or affect the performance of, algebraic operations, begin with \). In general, they may be contracted as far as is unambiguous, so that \(\)set message type on \(\) can be contracted as far as \)se\ m ty on

Convention 3. The symbol % refers to the most recently computed proper value (i.e. not of the Void domain). \(\%{(n)}\), or \(\%{n}\), refers to the value numbered \(n\), if \(n\) is a positive integer. If \(n\) is a negative integer, \(\%{(n)}\) refers to the value of the \(|n|\)th previous step. Also, \(\%{\pi}\) refers to \(\pi\), \(\%{e}\) to \(e \approx 2.718281828\) and \(\%{i}\) to \(\sqrt{-1}\).

Convention 4 (a convention of the library, rather than of the kernel). Parentheses – \(()\) – are used for grouping and function application, brackets – \([]\) – are used for constructing lists, and braces – \(\{\}\) – are used for constructing sets.

Convention 5. The \(::\) in \(x\) operator, used as in

\[ \text{Axiom object} :: \text{Axiom domain} \]

can be used to convert the object to lie in the specified domain.

Convention 6 (Of the library authors). The notation

\[ \text{list of variables} + \rightarrow \text{expression} \]

defines an anonymous function of those variables. It corresponds to the lambda-calculus expression “\text{\textbackslash{}variables.expression\textbackslash{}}”.

Convention 7. The names of Axiom functions are either special symbols (such as \(+\)) or complete English words strung together. In this case, every word after the first is capitalised. Thus \text{integrate} but \text{complexIntegrate}. In addition:

- all boolean predicates end in a \(?\), as in \text{odd?}, which tests if a number is odd
- all destructive functions which operate on data structures end in a \(!\), as in \text{reverse!}, which reverses a list destructively.

Conversely, the names of domains (and other constructors we will come to later) consist of English words strung together, all of which are capitalised, as in \text{IntegerMod} or \text{UnivariatePuiseuxSeries}.
Convention 8. Whenever a category, or domain, is being discussed in Axiom, the symbol \% stands for the domain in question, or for any domain from the category in question.

Convention 9. Axiom comments can be introduced by \texttt{--} or \texttt{++}. Those beginning \texttt{++} are intended for the user, and can be retrieved by the on-line help system.

Convention 10. The infix binary predicate \texttt{has} can be used to test if domains belong to categories, or if they have specified attributes.

Convention 11. Every Axiom constructor, i.e. functor or category, has an abbreviation, consisting of at most eight upper-case letters (seven in the case of categories). These serve two purposes: they can be used on input and output in order to make the names of the types shorter, and they denote the directory in which the corresponding Axiom library lives. The defaults for category \texttt{Cat}, with abbreviation \texttt{CAT}, are called \texttt{Cat&}, with abbreviation \texttt{CAT-}.

  Abstract: This paper describes the applications area of computer programs that carry out formal algebraic manipulation. The first part of the paper is tutorial and several typical problems are introduced which can be solved using algebraic manipulative systems. Sample programs for the solution of these problems using several algebra systems are then presented. Next, two more difficult examples are used to introduce the reader to the true capabilities of an algebra program and these are proposed as a means of comparison between rival algebra systems. A brief review of the technical problems of algebraic manipulation is given in the final section.

  Link: http://comjnl.oxfordjournals.org/content/15/4/362.full.pdf+html

  Abstract: We describe the methods available in the current REDUCE system for introducing new mathematical domains, and illustrate these by discussing several new domains that significantly increase the power of the overall system.

  Abstract: We extend a recent algorithm of Trager to a decision procedure for the indeﬁnite integration of elementary functions. We can express the integral as an elementary function or prove that it is not elementary. We show that if the problem of integration in ﬁnite terms is solvable on a given elementary function ﬁeld \( k \), then it is solvable in any algebraic extension of \( k(\theta) \), where \( \theta \) is a logarithm or exponential of an element of \( k \). Our proof considers an element of such an extension field to
be an algebraic function of one variable over $k$. In his algorithm for the integration of algebraic functions, Trager describes a Hermite-type reduction to reduce the problem to an integrand with only simple finite poles on the associated Riemann surface. We generalize that technique to curves over liouvillian ground fields, and use it to simplify our integrands. Once the multiple finite poles have been removed, we use the Puiseux expansions of the integrand at infinity and a generalization of the residues to compute the integral. We also generalize a result of Rothstein that gives us a necessary condition for elementary integrability, and provide examples of its use.

Abstract: This work is concerned with the following question: "When is an algebraic function integrable?". We can state this question in another form which makes clearer our interpretation of integration: "If we are given an algebraic function, when can we find an expression in terms of algebraics, logarithms and exponentials whose derivative is the given function, and what is that expression?". This question can be looked at purely mathematically, as a question in decidability theory, but our interest in this question is more practical and springs from the requirements of computer algebra. Thus our goal is "Write a program which, when given an algebraic function, will produce an expression for its integral in terms of algebraics, exponentials and logarithms, or will prove that there is no such expression".

Abstract: This paper discusses the design and implementation of MODLISP, a LISP-like language enhanced with the idea of MODes. This extension permits, but does not require, the user to declare the types of various variables, and to compile functions with the arguments declared to be of a particular type. It is possible to declare several functions of the same name, with arguments of different type (e.g. PLUS could be declared for Integer arguments, or Rational, or Real, or even Polynomial arguments) and the system will apply the correct function for the types of the arguments.

Link: http://staff.bath.ac.uk/masjhd/masternew.pdf

Abstract: While computer algebra systems have dealt with polynomials and rational functions with integer coefficients for many years, dealing with more general constructs from commutative algebra is a more recent problem. In this paper we explain how one system solves this problem, what types and operators it is necessary to introduce and, in short, how one can construct a computational theory of commutative algebra. Of necessity, such a theory is rather different from the conventional, non-constructive, theory. It is also somewhat different from the theories of Seidenberg [1974] and his school, who are not particularly concerned with practical questions of efficiency.

Abstract: This paper explains how Scratchpad solves the problem of presenting a categorical view of factorization in unique factorization domains, i.e. a view which can be propagated by functors such as SparseUnivariatePolynomial or Fraction. This is not easy, as the constructive version of the classical concept of UniqueFactorizationDomain cannot be so propagated. The solution adopted is based largely on Seidenberg's conditions (F) and (P), but there are several additional points that have to be borne in mind to produce reasonably efficient algorithms in the required generality. The consequence of the algorithms and interfaces presented in this paper is that Scratchpad can factorize in any extension of the integers or finite fields by any combination of polynomial, fraction and algebraic extensions: a capability far more general than any other computer algebra system possesses. The solution is not perfect: for example we cannot use these general constructions to factorize polynomials in \( \mathbb{Z}[\sqrt{-5}][x] \) since the domain \( \mathbb{Z}[\sqrt{-5}] \) is not a unique factorization domain, even though \( \mathbb{Z}[\sqrt{-5}] \) is, since it is a field. Of course, we can factor polynomials in \( \mathbb{Z}[\sqrt{-5}][x] \)

Abstract: AXIOM is a computer algebra system superficially like many others, but fundamentally different in its internal construction, and therefore in the possibilities it offers to its users. In these lecture notes, we will

- outline the high-level design of the AXIOM kernel and the AXIOM type system,
- explain some of the algebraic facilities implemented in AXIOM, which may be more general than the reader is used to,
- show how the type system and the information system interact,
- give some references to the literature on particular aspects of AXIOM and,
- suggest the way forward.

Abstract: Axiom is a computer algebra system superficially like many others, but fundamentally different in its internal construction, and therefore in the possibilities it offers to its users and programmers. In these lecture notes, we will explain, by example, the methodology that the author uses for programming substantial bits of mathematics in Axiom.

Link:  http://www.nag.co.uk/doc/TechRep/axiomtr.html

Abstract: This paper reports ongoing research at the IBM Research Center on the development of a language with extensible parameterized types and generic operators for computational algebra. The language provides an abstract data type mechanism for defining algorithms which work in as general a setting as possible. The language is based on the notions of domains and categories. Domains represent
algebraic structures. Categories designate collections of domains having common operations with stated mathematical properties. Domains and categories are computed objects which may be dynamically assigned to variables, passed as arguments, and returned by functions. Although the language has been carefully tailored for the application of algebraic computation, it actually provides a very general abstract data type mechanism. Our notion of a category to group domains with common properties appears novel among programming languages (cf. image functor of RUSSELL) and leads to a very powerful notion of abstract algorithms missing from other work on data types known to the authors.

Comment: IBM Research Report 8930

Abstract: The topic of this article is the symmetry analysis of differential equations and the applications of computer algebra to the extensive analytical calculations which are usually involved in it. The whole area naturally decomposes into two parts depending on whether ordinary or partial differential equations are considered. We show how a symmetry may be applied to lower the order of an ordinary differential equation or to obtain similarity solutions of partial differential equations. The computer algebra packages SODE and SPDE, respectively, which have been developed to perform almost all algebraic manipulations necessary to determine the symmetry group of a given differential equation, are presented. Furthermore it is argued that the application of computer algebra systems has qualitatively changed this area of applied mathematics.
